MDCCCLXXXV.

PRINTED AT THE "CEYLON OBSERVER" PRESS: COLOMBO, CEYLON: 1885.

TO OUR READERS.

In closing the Fourth Volume of the "Tropical Agriculturist," we have but to repeat what we have said on similar previous occasions, and to direct attention to the increased amount of useful information afforded, and to the great variety of topics treated in our pages. From month to month, we have endeavoured to lay before our readers the latest results of practical experience and scientific teaching in all that concerns tropical agriculture: and our ambition has been to make this periodical not only indispensable to the planter, but of service to business men and capitalists, never forgetting that agriculture trenches upon every department of human knowledge and science, besides being the basis of all human wealth.

While directing our attention chiefly to the products prominently mentioned in our title, we have never omitted to notice minor industries likely to fit in with tropical conditions; and our readers have an ample guarantee in the pages before them that, in the future, no pains will be spared to bring together all available information both from the West and East, the same being examined in the light of the teachings of commonsense as well as of prolonged tropical experience in this, the leading Crown and Planting Colony of the British Empire.

Dr. Trimen's Report on the Royal Botanic and Economic Gardens in Ceylon is republished in full, in a separate form, in the present volume. We are ready to give copious extracts from, if not to print *in extenso*, the Reports of all other Public Botanic Gardens situated in or near to the tropics which may reach us. Many of these Reports we already receive and utilize for the benefit of our planting readers.

A full and accurate Index affords the means of ready reference to every subject treated in this fourth volume which we now place in our subscribers' hands, in full confidence that it will be received with an amount of approval, at least equal to that which has been so kindly extended to its predecessors.

In conclusion, we must tender special thanks to our readers and contributors, and our wish is that all our friends may continue to write instructively and read with approval: for then indeed must the "Tropical Agriculturist" continue to do well.

A. M. & J. FERGUSON.

Colombo, 12th June 1885.

INDEX.

["Sup." refers to Dr. Trimen's Report which will be found bound in at the end of the Volume.]

D.

IRRIGATION IN CEYLON. ANCIENT AND MODERN.

On page 25 we give the valuable paper by Mr. Mosse, with a notice of remarks on it by Sir Wm. Gregory, Sir John Douglas, Mr. C. Bruce, C.M.G., and Mr John Ferguson. There is not much occasion for any comments of our own. We would simply restate our doubts whether Ceylon ever supported a greater population than now resides within its borders. When the conquerors from Northern India landed, the aborigines must have been few and their condition wretched, for the "Yakkhani" Queen had to feed her visitors on rice obtained from a wrecked ship. In after ages, and largely under the influence of Buddhism, many great and some splendid irrigation works were constructed. But invariably such construction took place in centres of population and in contiguity to the then seat of Government. As the court shifted its residence, tanks were either well attended to or neglected, and many of them fell into dissuse from desolating wars. When a large population existed in and around Anuradhapura, there is no evidence that the south-west of Ceylon, which owes its real prosperity to the introduction and cultivation of the coconut palm and other fruit trees and roots, had anything more than a scanty sprinking of population. The mistake even in regard to the eastern, northern and north-central portions of the island, is the supposition that all the great tanks were operative and simultaneously giving out water for irrigation. Of course our confrere, while dwelling on the importance of fruit and root cultivation to the people of Ceylon, did not mean to question the importance of irrigation to the dry and arid districts of the island where stored water is necessary even for fruit and root cultivation and for sanitary purposes. By all means let rice be grown where that is the most profitable cultivation, but let not other products be neglected. The North-Central Province is not suited for the coconut palm, but it is eminently so for the palmyra palm, which on the rising grounds should be interspersed with the rice fields. We believe it to be no extravagant anticipation that surplus rice from the North-Central Province will yet add profitable traffic to the Matale railway.

CULTIVATION OF CACAO IN THE EASTERN PROVINCE.

We received from Mr. Fielder of Batticaloa a large packet of chocolate pods with the following note :—

Batticaloa, 28th May 1884.

Dear Sir,—By today's parcel post I am sending you three packets, each of which contain two cacao pods picked from my young clearing at Mahaoya,* planted December 1880 and January 1881, and I would feel very much obliged if you would get some V. A. to give his opinion whether the pods are well-grown and matured. I may say it has been the dryest season I have known since I came to reside in the Eastern Province.—Yours truly,

S. FIELDER.

The pods were submitted for the experienced judgment of Mr. Wm. Jardine of Udapolla estate, and we congratulate not only Mr. Fielder but the colony on the highly favourable report, which is as follows :—

"The six cacao pods sent by Mr. Fielder are of our common red variety, are fully ripe and well-grown ; they are very fine, and I have seldom seen better; the bean looks plump and full, and, judging from the appearance of the pods, I should say that the soil and climate seem well-adapted to the growth of the cacao tree. I am curing the beans, and will send them to you in the course of a week."

* 36 miles from Batticaloa.

We imagine there are tens of thousands of acres of land inland from Batticaloa and in the east of the island generally, as also in the North-Central and Northern Provinces, well suited for this cultivation.

If Mr. Fielder would supply some figures for cost of land, seed, culture, wages of labour, &c., they would be interesting and useful. It would be well to state if the necessity of resorting to irrigation was at all experienced ?

COCONUT CULTIVATION.

The Reason for Writing.—As my opinions on coconut cultivation are still in advance of the common practice, I propose, in a series of short papers, to do justice to my own views, in the faith, that, so far as they are consistent with sound principles, they will gradually be accepted by the growing intelligence of those interested in this product, which, so far as the native industries of the Southern and Western Provinces are concerned, holds the first place. I have already opened the subject by a slight sketch of the commencement and progress of coconut estate cultivation, and I now proceed to treat the subject from the beginning.

Soils.—There are two kinds of soil on which coconuts refuse to grow to any profitable purpose, namely, thin washed gravels overlaying solid cabook and stiff clays, both of which should be avoided ; they will never pay for the labour; otherwise they are not particular. The richer the soil, they will grow the quicker and bear the earlier ; and the heavier and as a rule the longer it takes to bear, the smaller will the crops be. The best of all soils for coconuts are deep alluvial loams, on the banks of rivers, subject to floods that overflow on the neighbouring lands : in such situations, the crops are enormous ; indeed, a few acres of such land is a fortune to its owner, and, as the soil is particularly inexhaustible, it may go on for a century bringing in annually an income of R300 or more. Such pieces of land are generally small in extent, and widely apart. The next quality of soil is the brown loams, and they are only found in certain districts, and seldom extend into the higher uplands, where cabook gravel with varying proportions of loam prevails, and this is now almost the only description of land to be obtained. A loamy sand is a good coconut soil, and, with scientific cultivation, is only inferior to the alluvial and brown loams.

Lay.—The lay of the surface is an important factor in successful coconut cultivation; other things being equal, the nearer the approach to the level the better. Steep hill-sides are always poorer than neighbouring flats, and they become poorer from the base upwards, while a flat hill-top is always better than the steep sides. Darwin's work on earthworms describes the cause of this scientifically, and I need not bring my rushlight into the presence of a flambeau.

Nurseries.—Eight months before the plants are wanted for the field, a nursery should be put down with 50 per cent more seed-nuts than the number of plants needed, because there are always a greater or less number of the nuts that do not germinate, and all that have not germinated within five months should be rejected, as likely to carry the same slowness of growth into the field, and to this cause, chiefly, may be ascribed the inequality of the trees years afterwards, when there has been no difference of soil or treatment to account for it. The selection of the seed-nuts is an important affair, and should be done with great care. The best way is to select the trees from which the seed nuts are to be taken, and the rules to go by, are a mature healthy tree in heavy bearing, the nuts should be medium size, with thin husks, and should be ripe but not dry, as feeble plants alike result from insufficiently ripe and from over-ripe nuts. The coconut does not come true to seed; indeed, it would be difficult to find, in any field, two trees bearing nuts that are exactly alike, in colour, size and thickness of husk, but there is a better chance of getting a good type from a good tree than from taking seed indiscriminatingly. The ground for the nursery should be dug six inches deep, and formed into beds four feet wide, by removing three inches of the soil and laying it on the intervening spaces ; then pack the nuts, as close as possible, in the beds, with the stalk-end up, and return the earth dug out, to fill the spaces

between them, cover the beds with straw or grass, and water, when there is four or five days without rain.

Lining.—The clearing should be completed by the end of February, and the lining and holing begun with the first March rains. Experience has settled 25 by 25 feet as the proper distance. Great care should be taken in lining, not that a foot or two one way or another will affect the ultimate crops, but no one with good taste can wish to leave behind him a lasting memorial of careless work, when a little more trouble will record his skill for a century.

Holing.—Coconut holes cannot be made *too large*, say 3 by 3 by 3 feet, and they should be filled in for half their depth, with soil from the surrounding surface. It is important to give the plant the means of a fair start, and 18 inches of loose rich soil, below and all round it, is the best available means to that end; indeed a plant so reated, will gain several years on one placed in a one-foot hole.

Fencing.—The next operation, or rather an earlier one, is a fence sufficient to keep out cattle. There is generally enough of wood on the ground to form a strong rough fence that will serve the purpose for three years, and the planting of a live-fence may be deferred till that begins to fail or till there is leisure to attend to it. There are many plants that may be used for fencing, but that in most common use is *erandu*, the efficiency of which depends entirely on the maintainance of cross-sticks tied to each plant, and that requires to be renewed, at considerable expense, at least once a year. Sapan is straggling and unreliable, and is given to resentment when any attempt is made to train it. The *Bide-a-wee* thorn would make an excellent fence, but I am not aware, that it has ever been tried, or even that it will submit to training, more than to external meddling. The kaju makes a very effective fence, in the Kadirana cinnamon estates, but, like all other live-fences, it needs training and labour to keep it in order. The fact is that plants in great variety may be trained into a good fence, but all require labour and care.

Secondary Crops and Goyas.—I have no objections to growing secondary crops on a young coconut field; but the value of the crops should cover the cost of labour at current rates, restore (in the shape of manure) the fertility they take out of the land, and yield the owner some return of profit for his time and trouble. Those conditions are not met by the usual goya course—kurakkan, cassava and sweet potatoes. These products have only a local value, and are only used by the poorest of a poor population. The kurakkan crop is the most exhausting that can be taken off land, consuming more of the nitrates and phosphates than many other products of much greater value would do; and if cassava and sweet potatoes are less detrimental to the soil, their money-value is hardly worth cultivating. By the employment of goyas, the land-owner saves the payment for felling and clearing his land, under R10 per acre on the average; he receives a few rupees per acre as the land-share of the crops, and he need be nothing out on account of cultivation for the first two years, and all that he gets will seldom aggregate R30 per acre. Per contra, he loses an unknown measure of the freshness and fertility of his soil, which, because it is unknown, he never counts; yet it is a real element in the account. Were I interested in the question, I would submit a sample of kurakkan to a chemist and thus ascertain the money-value of the elements it removes, but, as I am not, and never intend to be, I am not prepared to go to the expense. I would be more tolerant of goya cultivation, if they would grow some other crop than the everlasting kurakkan. Dry chillies, for instance, are worth R25 per cwt. and average jungle soil will certainly yield 3 cwt., most probably more, whereas the money-value of the best kurakkan crop is under R30 per acre. If the proprietor starts his estate with capital enough to do his cultivation full justice, there are many ways in which this case be done with greater profit than employing goyas.

Secondary Crops and Alternative Treatment.—As secondary crops, such products as croton and anatto would be much more profitable than goya culture; the former sells at 70s to 80s in the London market, and I believe there is always a paying market for the latter, though I found no quotation in the *T. A.* In fact, there are many things that could be grown with profit on the land, and with small injury to the coconuts, during the long years the cultivator has to wait; and if some of the profit be expended in fertilizers for the secondary crops, the coconuts will partake. The only thing to be avoided in such case is growing anything running up to shade the coconuts. If it is preferred to devote the whole strength of the land to the coconuts and bring them into early bearing by forcing the best way is to sow the land with guinea-grass, stall feed as many cattle as will eat it, and keep putting the manure so made to the most feeble, and lagging trees in the field. By this means the trees may be brought into heavy bearing years earlier than they would yield a nut if left unaided even by tethering cattle on the natural pasture, so that they cannot reach the young trees; and by digging in the droppings near the plants, much may be done in hastening bearing. Such operations would not, indeed, bring any fresh fertilizing matter into the land, but, by concentrating such as was already there and placing it within reach of the roots, the tree would be strengthened and stimulated to push out roots more rapidly in search of further supplies of plant-food, resulting in quicker growth and earlier maturity. I would be glad to convince every owner of a young coconut property that it is more to his advantage to treat his trees generously and get them into bearing in seven or eight years than by grudging and withholding a very moderate annual expenditure, having the trees straggling into bearing over the whole ten years between the tenth and twentieth, and that twenty acres fairly treated throughout will, at ten years' time, be a more valuable property than one hundred that has been starved and neglected. It has been sadly against a progressive improvement in the cultivation of coconuts that the proprietors are almost to a man traders, clerks and professional men who have thus invested their savings, but who acquire no knowledge of the habits and requirements of the plant.

Enemies of Coconuts: Wild Pigs.—If there are wild pigs in the neighbourhood of newly-planted coconuts, they are very destructive, and I know no effectual means of circumventing them. A secure fence would do, but I have never seen a sufficiently secure fence. Night-watching is of little use in dark nights, while battue-hunting is not easily organized, and is seldom if ever effectual in either exterminating or driving the herd away from the locality. This danger is, however, passing away as the country is opened, though the herds often linger in their old haunts as long as they have cover. It is only within the first six or eight months that the plants are liable to this evil.

White Ants.—White ants are very destructive to young plants for the first year or till the roots have so far penetrated the soil that the plant is independent of the nourishment derived from the husk. Many things have been tried as remedies with more or less success, but the only thing that effectually settles them is arseuic. The difficulty is in the application of the minute quantity necessary: half-an-ounce of arsenic would poison all the termites in a hundred acres if they could be induced to partake of it. From Queensland we are told that a paste of flour, sugar and a small quantity of arsenic distributed about their nests will clear a whole neighbourhood. No doubt the smallest atom of the poison will suffice for a single ant if it can be induced to take it. This information was accompanied with a piece of natural history that, if true, would render dealing with this pest extremely simple. It is maintained that white ants eat the dead, so that when you have succeeded in poisoning one, you have provided for the destruction of a thousand. I would recommend the following process in the case of coconut plants:—Take a tub, fill it nearly full with fresh water, dissolve in it a quarter of a pound of sugar to each gallon of water, add flour till the mixture is of the consistency of whitewash, add two grains of arsenic for every gallon of water. Mix thoroughly and keep stirring while the coconuts are being dipped in the mixture. Lay the nuts in the sun to dry the thin coating of the mixture that adheres to their surface, and then plant. There is no doubt whatever that the insects will be destroyed if they eat the mixture, and it will be impossible for them to reach the coconut without doing so.

Cattle.—Cattle eat the leaves of young coconuts, and for the first three years must be absolutely excluded, or securely tethered, out of reach of the plants. They are out of danger when the animal can no longer reach th

lately-developed leaves, and they do not meddle with the older growth.

Porcupines.—Porcupines are not common in coconut districts; but where there is even one in the neighbourhood of coconuts that have lately formed stem, it is very destructive. Its mode of operation is to eat through the stem and commence on a fresh tree on each nocturnal visit. Wherever it puts in its appearance, it should be hunted down and killed at any cost.

Kurumiriya or Black-beetle.—When the coconut has tolerably thriven during the first year and has any available cabbage in the heart, the black-beetle commences operations. He bores his way through the outer covering of mature leaves, gorges himself on the tender undeveloped heart, and then departs till he is again an hungered, when he returns and effects a fresh entrance. When he find a tree especially to his taste, he returns so often, that, when the cut leaves come out, the foliage has a most ragged and forlorn appearance. All this work is done in the night, and he is very rarely found in the tree during the day, but, when he happens to delay his departure till daylight, he remains in his retreat all day, and, if discovered, may be slain there with a barbed wire. I have lately seen kerosine oil tried, but without any effect. The insect cares not for stinks, it cares not for smoke, it cares not for anything man can do to circumvent it. The only way I know of reaching this pest is to hunt up and destroy the grub in every dunghill, every accumulation of decayed vegetable matter or rotten tree in the vicinity. A specially favourite breeding-place is an old heap of cinnamon scrapings on estates, where a score of great white grubs may be found often in a cubic foot of this matter.

Red-beetle or Kandapanuwa.—The next foe that attacks the coconut is the red-beetle. Unlike the large black species, it has no alimentary apparatus whatever in its perfect state, the sole business of that stage of existence being the propagation of its species, and its breeding ground is the tender stem of the young coconut tree. It is furnished with a stiff horn in front, with which it is supposed to puncture the outer coating of the stem, and deposit one egg in every opening so made. As soon as the grub is hatched, it begins to eat its way inwards and upwards, enlarging the opening as it grows till it attains its maturity as a grub. It then returns from the centre of the stem, and just within the outer rind, which it reduces to the thickness of foolscap, it wraps itself in a cocoon of the fiber of the stem and there awaits transformation; when that occurs, it is easy for it to break through the thin partition that divides it from the outer air. The coconut is in danger from this insect, from the time it shows stem till it begins to bear. The body of the young stem is a mass of matter of the same nature and consistency as the heart of a cabbage stalk, which hardens from the surface inwards. Nature has provided for the protection of the tender young stem in the close fit of the imbricating leaves, which enclose it on all sides, and retain their hold till they rot in situ. The red-beetle cannot penetrate the leaf-imbrication, and, when the older once decay in the course of nature, the stem has become too hard for its operations. A tree here and there may be lost from an accidental wound or from some defect in the fitting of the leaf-sheaths, but it is only where the good taste of the planter has impelled him to trim the leaves that any serious damage has been done to a field. All the leaves should be left on the tree till Nature disposes of them at her own time and in her own way. Nothing that can be done to a cocoonut tree above ground can be anything but injurious. As soon as it is discovered that the *kandapanuwa* has effected an entrance, the tree should at once be rooted out, chopped up and burned, as there is no more hope for it, and it is not well to leave a breeding-ground for so formidable a foe.

Rats.—When an estate is in bearing, it often becomes infested with rats. They attack the half-grown nuts, make a hole through the husk and shell, and, when they find a tree with fruit to their taste, they appropriate its whole produce. The native cultivators put a ring of tar round the stems, which they say is too smooth to give them a foothold in climbing, and they sometimes keep a donkey in a field, whose braying is supposed to frighten them to the extent of driving them out of hearing of the awful sound. The tar-dodge may possibly be effective, but the trees should all be cleared of rats in the first place; every tree in the field should be tarred and all other means of getting up removed, for they can freely pass from tree to tree, and, when they have sufficient food and drink and the materials of a comfortable nest on the spot, they have no occasion to visit on *terra firma*. As for don key-braying, it is probably one of the myths to be found in the folklore of every land. It is a misfortune of the coconut planter that all his foes are nocturnal in their habits, so that in dealing with them he gropes in the dark. Would the rat only come out and work in the day, the infested trees could be watched, and a charge of sparrow-shot bestowed on the robbers. Attempts have been made to poison them, but, while they have their will of the young coconuts, the most savory morsel will not tempt them.

Locusts.—The locust is so rare in Ceylon that it is hardly worth mentioning, but it sometimes appear in small numbers, and the coconut-leaf is a favourite. They devour all the leaflets, leaving the bare midribs, so that, when they have done with it, it has a very wintery look.

(*To be continued.*)

SIR JOSEPH FAYRER ON THE RAINFALL AND CLIMATE OF INDIA.

Here, in Ceylon, we have no absolutely rainless region, our extremes running from 250 inches in Ambagamuwa to 30 at Mannar. In India, their extremes of rainfall vary from between 500 to 600 inches (610 fell at Cherapunjee in one year) down to almost *nil*, for there are places in Rajputana, Sind and Beluchistan, where rain does not fall for years in succession, and then in quantity not exceeding a few inches. One of the great problems, therefore, for the rulers of India and Ceylon, is how most usefully and economically to divert the excess of aqueous treasure in some portions of their territories so as to benefit by irrigation other portions which are dry or absolutely arid. Much has been done by means of canals and tanks, and we cannot help thinking, that, besides utilizing surface water, much remains to be done in many parts of India and in some parts of Ceylon, to compel the earth to yield up her stores of subterranean fluid by m ans of artesian wells. Dr. Fayrer spent his first year in India at Cherapunjee, and he states that the 610 inches he then registered gave him an interest in rainfall that he has never lost. No wonder, for the fall was within two inches of fifty-one feet. The contrast to this is a fall of not more than two inches in four years in the great desert regions abutting on the Arabian Sea. Looking at the map of India, we find a rainy region of from 30 to 75 inches average, extending round the coasts of the Bay of Bengal, from Ceylon and the Malayan Peninsula in the south, on each side, to the mouths of the Ganges, and away up the sides of the Himalayas where, at Darjiling, the fall rises to 250 inches and more, the deposit increasing up to 7,000 or 8,000 feet, and then rapidly decreasing until at great heights there is no rainfall, because the rising atmosphere has already been compelled to part with most of its moisture. Rainfall, exceeding 75 inches and up to 300, extends from the south-west of Ceylon along the western coast of India, until with Cutch in Sind the desert region of under 15 inches and down to nothing commences. Of course, within what is marked as the rainy region, there are many tracts of country which show deficiency of rainfall, because of their position on the lee-side of those mountain ranges or "Ghauts" which in India, and in Ceylon also, are the great agents in cooling the atmosphere and compelling it to deposit its superabundant moisture. But it is, as we have said, the lower ranges of vast mountain masses, the Khasiya Hills for instance, in advance of the grand Himmalayan ranges, which being first met by the

rain clouds are first and most liberally served. In India, not only are the hot and dry regions unhealthy, but so are even large portions of the hill-country, where excessive rain at one period of the year is followed by droughts sometimes extending over eight months. The salubrity of the mountain and hill regions of Ceylon above 2,500 feet, and also of much of the plain country, is owing to the position of the island with reference to the two monsoons, so that the rainfall is not only copious but well-distributed over the year. The insalubrity of the regions around Hambantota in the south of the island and Mannar in the north is not so much due to the low rainfall of 30 inches, as to the fact that nearly the whole of the fall takes place in about four months while the rest of the year is hot and dry, conditions evidently favourable to the production of what is called "malaria" (*mal-aria*, bad air) and the resulting fevers, which are so often fatal or which make life a burden. We know of the case of a doctor and his wife in Rajputana who have buried seven out of eight children born to them, and the eighth is probably only alive because sent early to England and kept there, the parents themselves having simply struggled on against repeated and wearing attacks of fever. Most of our stations in Ceylon are healthy, while in India many are insalubrious and a number deadly. At such stations there will be comparative immunity from disease for many years, and then a bad year will come, disease being generally coincident with drought. In Kurunegala, in the early days of British occupation, one-third of the European population have been swept away in one season. Things are not so bad now but still Kurunegala fever is dreaded and rightly so. Trincomalee had once a very evil reputation, but it is now claimed for the eastern port that it is healthy. But this must be merely comparative. The difference between Trincomalee and Colombo, apart from quantity and distribution of rainfall, is, that, for the larger portion of the year, the wind at Trincomalee is a land-wind. For nine out of the twelve months, Colombo is refreshed and purified with sea-breezes. The result is that Colombo is, and with proper sanitary precautions ought always to be, one of the most salubrious towns in the world. None of the capital towns of India can compare with it in this respect. Dr. Fayrer's paper was suggested by one read by Mr. Bateman before the Victoria Institute on the rainfall of the British Isles and its influence on human health and hardihood, on the fertility of the soil and the production of food. Mr. Bateman is one of the greatest authorities of our time on hydraulic engineering, and he occupies the same position in regard to the Colombo water works (now advancing to completion) as Sir Hutton Gregory does towards our railway system. As bearing on the question of the fall and distribution of rain, the geographical position and physical peculiarities of India were, of course, described. The gaseous atmosphere which surrounds the globe is described and the causes and effects of evaporation and condensation on which rainfall depends. We quote as follows :—

The ocean is the great source whence atmospheric moisture is derived ; it is the great bourne to which it all returns. As the wise king said,—"All the rivers run into the sea, yet the sea is not full ; unto the place from whence the rivers come, thither they return again."

The atmosphere is the great sponge that soaks up and holds the watery vapour, which, when condensed falls into the ocean, or on to the earth, to fill the rivers, to sink into the ground, whence it rises again in springs, collects in wells, lakes and pools, or runs off in streams and rivers, diffusing itself everywhere, ministering to the wants of nature, and supporting life and organization ; finally, to return to the ocean again to rise in vapour, and repeat the endless circulation, without which life would be extinct, and the earth reduced to the condition of the moon, or of some effete worn-out world.

Water is always evaporating; expose a cup of it to the air and it will soon disappear,—all the sooner if the air be dry and warm. So will ice or snow, in regions where the cold may prevent it from melting, but not from evaporating ; it is not lost, but assumes the impalpable form of vapour, and mingles with the air. This process is going on wherever there is water, but more especially from that part of the ocean which lying near the equator, is subjected to the continued heat of the vertical solar rays. Here vaporization is most active, and the warm air, saturated with moisture, rising in constant currents to higher regions, is replaced by colder and heavier currents rushing in from towards the poles ; in turn to be heated, charged with moisture, ascend, and so keep up a constant circulation, making the equatorial rain ' belt the great distillery of nature

"The wind goeth towards the south, and turneth about unto the north ; it whirleth about continually, and the wind returneth again according to its circuits." hese perennial northern and southern currents, or trade winds getting their easterly direction from the earth's rotatio, are always blowing towards the equator ; whilst there is a regularity of climatic phenomena unknown beyond the tropics, where many and varied changes occur.

The northern hemisphere, containing much more land than the southern, is subject, on account of deflected ocean currents and "thermal" changes, resulting from the varying radiations of the land and sea to greater perturbation of the conditions that determine the formation and distribution of aerial moisture and other meteorological phenomena ; and it is to one of the most remarkable of these, the monsoons of the Indian Ocean, that the climate and varying seasons of India owe much of their peculiar character.

Then comes the passage about the monsoons which we have quoted, and Sir Joseph Fayrer proceeds to describe the main physical characteristics of the vast rainfall area of India. A knowledge of the general facts connected with India may be taken for granted on the part of our readers : such as that it has a coast line of 4,000 miles ; that the direct length in two directions is 1,900 miles ; that the superficial area is 1,500,000 square miles, equal to the whole of Europe excluding Russia ; that it contains the highest mountains in the world, covered with eternal snow, and many great rivers with several watersheds. We now quote :—

This vast country, which has nearly two hundred and fifty millions of inhabitants, of races more ethnically distinct and more numerous than those of Europe, has, owing to the nature of its physical geography and the extent of its area, every kind of climate, from that of the Torrid to the Arctic zone ; possessing lofty mountains, elevated table-lands alluvial valleys, desert tracts, and plains ; noble rivers, extensive swamps, jungles, and magnificent forests ; it has characters that invest it with peculiar interest for the meteorologist ; for, as Mr. Blanford says, "it offers peculiar advantages for the study of meteorology, exhibiting at opposite seasons of the year an almost complete reversal of the wind system and of the meteorological conditions depending on it. Its almost complete isolation in a meteorological point of view from the rest of the Asiatic continent by the great mountain chain along its northern border simplifies to a degree almost unknown elsewhere the conditions to be contrasted, by limiting them to those of the region itself and the seas around. India also presents in its different parts extreme modification of climate and geographical feature. In its hill stations it affords the means of gauging the condition of the atmosphere at permanent observatories up to a height of 8,000 feet. The periodical variations of temperature, vapour, tension, and pressure, both annual and diurnal, are strongly marked and regular ; and these changes proceed so gradually that the concurrence and inter-dependence of these several phases can be traced out with precision." As regards climate, India may be divided into :—1. Himalayan, including Bhotan, Nepaul, Gurhwal, Cashmere, and Cabul. 2. Hindoostan, which extends along the foot of the Himalayan range, and includes the alluvial plains of the great rivers Ganges and Indus, with their numerous tributaries, as far south as the Vindyah mountains. 3. Southern India, or the Deccan, which consists of elevated table-lands, littoral plains intersected by numerous rivers, moun

taiu ranges, and isolated hills. The Aravulli and Chittore hills, the Vindyah chain, rising to over 2,000 feet, covered with forest vegetation, with its off-set the Satpooras, traverse the continent connecting the Eastern and the Western Ghâts.

The rainfall varies according to latitude, elevation, and physical characters of the country, Northern India being less influenced than the Deccan by the south-west monsoon. The climates also vary; but in the plains of Hindoostan and the table-lands of the Deccan, the heat is intense, though often greatly modified by moisture. The effects of a dry or damp atmosphere at the same temperature, however, are very different. Dry air, in motion, at a temperature of 100°, is more tolerable than stagnant air loaded with moisture at 80°. The hot dry winds of Northern India are more endurable than the cooler but saturated atmosphere of Lower Bengal or parts of Southern India. [and Ceylon.—ED.]

The *mean* temperature of a few well-known stations is as follows:—

Calcutta, 8 feet above sea level, is in May (hottest month) 89°; in January, 70°; but it ranges between 45° in the coldest and 92° in the hottest months.

Madras, sea level.—June (hottest), 88°; January 76°. Range, 72° to 92°.

Bombay, sea level.—May (hottest), 86°; January, 74°. Range, moderate.

Peshawur, 1,056 feet above sea level.—June and July (hottest), 91°; January, 52°. Range, great.

Punjaub, 900 feet above sea level.—June (hottest), 89°; January, 54°. Range, from frost to intense heat—110° and more.

Bangalore, 3,000 feet above sea level.—May (hottest), 81°; January, 69°. Range, moderate.

Poonah, 1,089 feet above sea level.—May (hottest), 85°; January, 70°.

Belgaum, 2,200 feet above sea level.—April (hottest), 81°; May, 78°; June, 75°. December (coldest), 70°.

The coldest months are December and January; the hottest, April, May, and June.

There are fluctuations in temperature owing to hot, dry winds, sea and mountain breezes, great river basins, the presence of forests, tracts of jungle and vegetation, arid treeless rainless deserts, which give local peculiarities of climate; but it may be said, generally that there are three distinct seasons in India—the hot, the rainy, and the cold,—which vary in duration and times of setting in; but approximately the cold season extends from November to March, the hot from March to June or July, and the rainy season from that to October and November, these seasons being greatly influenced by the monsoons. The south-west monsoon commences with storms of thunder and wind, which are soon followed by the bursting of the rain on the Malabar coast, in May, but reaches regions further north later in the year. Its force and influence, indeed, are well-nigh spent ere it passes the twenty-fifth parallel of north latitude. The Carnatic and Coromendal coasts, being sheltered by the Western Ghâts, are exempt, when the west coast is deluged with rain.

About Delhi and in the north-west the rains begin towards the end of June, and fall in diminished quantity. In the Punjab, near the hills, the rainfall again increases; but in the Southern Punjab, and in the Great Desert regions, there is very little rain,—in some parts none. There are belts or tracts of country commencing in Sind and the north-west, almost rainless, or with a rainfall as low as two inches; whilst the highest fall is at Cherra Poonjee, in the Khasia hills, on the north-east frontier, where 600 inches fall in the year. Next to this, the Western Ghauts have the greatest rainfall; at Mahableshwar 253 to 300 inches, and on the Tenasserim coast 180 inches fall yearly. The provinces in the North-east receive rain in rather a different manner; the wind which brings the rains to that part of the continent blows from the south-west, over the Bay of Bengal, till, meeting the mountains it is deflected. The prevailing wind, therefore, in this region is south-easterly, and from this quarter Bengal and the Gangetic valley receive their rain; when it reaches the mountains in the north-west, it is compelled to part with more of its moisture.

Near the sea, where the land is low and the temperature high, very little rain falls; at Kurrachee it was, in 1879, 1·92 inch. In inland districts, as at Peshawur, in 1879, only 0·84 inches fell; whilst the rainfall in Calcutta averages 63; in Madras, 48·50; in Bombay 74; in Delhi, 27·5; in Meerut, 27; in Lahore, 21; in Mooltan, 7; in Benares, 37; in Bellary, 18; in Bangalore, 35; in Poonah, 27; in Belgaum, 49; in Kamptee, 22; in Akyab, 198. The amount of humidity in the air also varies greatly. Flat hot plains, like Scinde, where there is little or no rain, have an atmosphere almost saturated, and on some of the lower mountain ranges, in Bengal, and in many districts near the coast in Southern India, the air is very damp. But the elevated table-lands of the Deccan and Central India, and the hot sandy plains of North-west India, have a dry air during the months of May and June, which blows like a furnace blast, heated and desiccated by the burning country over which it has passed!

The north-east monsoon commences gradually in October, and is attended with dry weather throughout the Peninsula generally, except on the Coromandel coast, where it brings rain from the Bay of Bengal, between October and December, after which it is dry until March, when it gives place to variable winds, which last till about June, when the heat is great and the tendency is then from the south. About the end of May the south-west monsoon again sets in, bringing a few showers, known as the lesser rains, before the regular rains set in. In the hill stations of Darjeeling, Mussoorie, Naine-tal, Murree, Simla, and generally in the elevated provinces of the lower ranges of the Himalayas, also at Ootacamund, Conoor, Wellington, Mahableshwar, in the Neilgherries, and Ghauts—stations at elevations of 5,000 to 7,000 feet—the climate is genial, the rainfall moderate, it is healthy in summer, and almost as bracing in winter as Europe. These are favourite health resorts, and may, perhaps, become the sites of future colonization, for it seems probable that there the European will thrive and continue to reproduce his race, which it is said would cease to exist in the plains after the third generation.

After quotations from old travellers about the equally fierce summers and winters of India, Sir Joseph Fayrer proceeds thus:—

A glance at a hyetographical map of India shows that there are areas of rainfall of various degrees of irregular form and extent, corresponding to the latitude, physical characters of country, and proximity to sea or hills. Let me briefly describe them.

In the north-west corner of India there are arid regions, which have a rainfall of less than 15 inches; in many parts of it, indeed, it is much less; whilst the desert tract of the Thur is to a great extent rainless. This area includes Sind, part of the Punjab, and Rajputana. Then there is a zone with an annual fall of between 15 and 30 inches, surrounding the arid region on the north and east in a belt of 100 to 200 miles wide, which includes Delhi and Agra. This is the northern dry zone. The upper parts of the valley of the Ganges, Central India, and the eastern coast of the Madras Presidency, have a fall of between 30 and 60 inches.

There is a southern dry zone, which extends from Nassick to Cape Comorin, at a distance between the two seas. The deltas of the Mahanuddi and Ganges, and the lower part of the Gangetic Valley, have a fall of between 60 and 75 inches. There are two belts of excessive rainfall,—one extending along the Aracan coast, from the mouth of the Irawaddy up the valley of the Burhampootra. The other, on the west coast of India, from Cape Comorin to the Tapti—from the seashore to the summit of the Ghauts! It is in these regions that the most remarkable falls occur, for the reason that they are placed in the direct course of the south-west monsoon, catching its first impact at heights where vapour is most readily condensed into rain. Mr. Bateman told us that at 2,000 feet the greatest condensation takes place in our islands; it is at a greater elevation in India, and the most striking illustration is found at Cherra Poonjee, in the Khasia hills, where, at 4,000 feet above the sea, 600 inches of rain fall in half the year. Here the locality is on the edge of an abrupt mountain ridge and plateau, situated about 200 miles from the Bay of Bengal, the intervening country being flat alluvium, covered with rivers and swamps. Over this the south-west monsoon blows, laden with moisture from the ocean, which is increased by absorption from the wet country over which it passes. On the plateau of Cherra

Poonjee the first condensation takes place, and the fall is so great that in a few weeks the plains of the Sylhet district, lying at the foot of the hills, are converted into a sea; whilst a few miles inland, and at little greater elevation, the fall is reduced to less than one-half. I spent my first year in India at this station, and the 610 inches I registered on that occasion gave me an interest in rainfall that I have never lost.

At Mahableshwar, in the Western Ghauts the conditions are somewhat similar, but there the fall is less, amounting only to about 300 inches. In these instances, we have all the conditions favourable to the production of rain in the highest degree, but these excessive rainfalls in certain elevated regions are quite local, and no more represent the average rainfall of all India than does the dryness of the desert tracts in the north-west; or the heavy fall on the hills on the west coast of Britain, in Cumberland or Scotland, the average rainfall of Great Britain. There is, however, an analogy between India and Britain in this respect, much as they differ otherwise in the nature of the distribution of rain, that the heavy falls at Cherra Poonjee and Mahableshwar are paralleled by the heavy falls on the slope of Ben Lomond, Glengyle, or the Cumberland hills; while the heavy rainfall on our western coast—the result of the warm moist air coming from the Atlantic and Gulf Stream—resembles the south-west monsoon, which deposits its heavy rain on the Western Ghauts and on the coast of Aracan—proximity to the Equator and high temperature in the latter cases making the effect so much more striking.

The average annual rainfall in Equatorial regions is, I believe, about ninety-five inches; in the temperate regions thirty-five inches, that for the whole of Tropical India is considerably less; while for Hindostan it would be reduced to a lower figure if we include in the average the almost rainless Thur desert; but, if the rainfalls of the Himalayan be included, the average would, no doubt, be considerably raised. The problems presented by the rainfall are of a comparatively simple character in Southern India and Bengal, where the influence of the monsoon is prominently felt; but in the northern regions of Hindostan, where the influence of mountains, river basins, and the desert come into operation, there must of necessity be perturbation of the direction of the air currents and of the amount of rain. Further observations will, no doubt, in time throw much light on these points.

Then follows a table of rainfall provinces, varying in averages from 170·73 inches in Tenasserim down to 9·24 in Sind and Cutch. There is a very interesting section on irrigation, which we must pass over for the present, but we must quote what Sir Joseph Fayrer says of the influence of rainfall on those diseases which he spent his life in India in treating:—

Another point of view from which meteorology is most important in its bearings on the material prosperity of India is the effect which it exercises over the sanitary condition of the people. There can be little doubt that public health is greatly affected by the rainfall, and that fluctuations or extraordinary departures from the normal state are attended by fluctuations in the standard of public health. The diffusion and activity of epidemics are probably influenced by it. It would be saying too much, perhaps, to assert that the fluctuations in the death-rate are altogether due to variations in the rainfall, but that they are to a great extent influenced by it seems to be proved by what obtains all over India.

The following * appears to have been ascertained in relation of climate to epidemics:—

1. If epidemic cholera be about, its intensity will be increased by continued dryness, evaporation, and high temperature. If cholera exists under this form, heavy rain will greatly diminish it, or wash it away.

2. Dryness, heat, and rapid evaporation reduces the intensity of fevers. Rain following, greatly increases their intensity. But the effect is not what can be called immediate. The rain must accumulate and the ground be soaked; as soon as drying up begins fever augments until the evaporation reaches a certain intensity, when it declines. It is not so much the great amount of rain as the soaking and saturation that does the mischief. In some places fever declines very much when the country is completely flooded, but increases in intensity when the rain ceases, and drying up begins.

3. Smallpox in India does not appear to be related to rainfall. It augments with increase of heat, and so continues till colder weather arrives, irrespective of the amount of rain.

4. Rain with cold and high temperature range appears to augment the liability to bowel diseases, but not to a very great degree.

Dr. Fayrer takes the popular idea of the influence of forests on rainfall.

An interesting discussion followed the reading of the paper in which Dr. Cheevers said that when he went to India the "rains" could be depended on to commence on 20th June at Calcutta, but that since trees had been so largely cut down there were great fluctuations. This is attributing great results to small causes. The truth is, people did not record observations carefully in the old times, one meteorological phenomenon recorded by a native doctor being an "east-west wind." Another filled the rain gauge from a jug of water when his superior was expected. Col. Grant, the African traveller, said:—

I may allude to the equatorial region of Africa, in which I was with Captain Speke, where we had only, 49 inches of rain. The altitude of the country is 4,000 to 5,000 feet and as one goes northward to 5° north latitude add 2,000 feet altitude, the country is more of a desert, and resembles parts of Ceylon in there being a small rainfall. In the region of 3° south latitude, where the rains reach both the Congo and Nile, the fall of rain may be 60 inches,

The subject is so interesting, especially at present, when we are waiting for the advent of the biggest of all big meteorological phenomena, the south-west monsoon burst, that we need make no apology for the length of our extracts. The difficulty with us, indeed, was to refrain from marking more for extract than we have done from Sir Joseph Fayrer's most interesting paper.

STRATHELLIE TEA ESTATE AND ITS MACHINERY

are thus described by a correspondent in the local "Times": we persume the circular saw is employed mainly to cut timber into staves for tea-boxes:—

But for the oppressive heat, it is pleasant and instructive to go over a well-ordered tea-factory, such as the one I was that day shown. Few estates that I have as yet been over have so well appointed and excellent machinery and accommodation as Strathellie. Two of Jackson's rollers, one of his largest to hold 400 lb leaf, a smaller one, holding about 80 lb, a full-sized Ansell's sifter, and two large Siroccos seemed sufficient for all requirements of the estate, at least at present. Owing to the lack of water the large wheel was set apart to drive the largest roller only, the motive power for the remaining machinery being a small 4-horse power steam engine, which drove the sifter, the smaller roller, and a circular saw. The noise and the heat when all this machinery, supplemented by the shriek of the circular saw is in full swing, is quite indesirable.

I was unfortunate in not seeing Ansell's sifter at work, for, I believe, this is the only one in the island; and some time ago the Superintendent, Mr. Scovell, gave Messrs. Davies & Co. the Agents for it a very good report of the work it had done. The great fault of Jaokson's machines appears to be the excessive friction and grading the tea undergoes in its many journeys up and down the whole length of the machine. This is obviated in Ansell's as much as possible, and a fan at one end drives the fannings out of the tea into a sack at the other end. I wonder that more than this one have not found their way up-country, but no doubt it is early yet. It seems to me that those with tea machinery for sale have no field in India like that Ceylon now offers for the sale of their various patents. As regards rollers, I do not think I am far out when I say that the majority of planters prefer Jackson's to any other,

even to Kinmond's. The ease with which even the largest size move, and the perfection of the roll of each leaf, are excellent, and testify alike to the finish and stability of Messrs. Marshall's workmanship as well as the ingenuity of the inventor. Notwithstanding the warmth, it was not particularly good withering weather, and the leaf took a considerable time before it had attained that indescribable silky softness which proclaims it ready to roll. The spacious upper story of the factory was not nearly of sufficient size to wither off all the daily leaf, particularly in bad weather, so a large withering house had to be erected near the store for this purpose, and was crammed with leaf. I was amused at the ingeniousness of a little wooden tramway on which a large box travelled up and down between the trays of withering leaf in the floor above the factory. Into this box the leaf when withered was placed and run up to the end of the store to a hole above the hopper of the large roller, into which its contents were emptied. So complete was this piece of work that in order to allow of the box travelling down the other row of trays a miniature turn-table had been fixed at each corner of the room.

Ramaswamy must rather like the work in a tea factory. He is not obliged to be out in the cold and rain, and seldom gets half-named. The work is not heavy, and when once he has mastered the intricacies of the work he has to perform, it is a mere rule of thumb. The happy and contented look of the coolies squatted across a double reaper, sifting tea by hand, is not to be matched anywhere that I have seen, and even those working the Siroccos which must be the most unpleasant of all work in the factory, seemed rather to enjoy the fearful heat than not, though the perspiration was rolling off them in the most alarming manner. The simplicity of these Siroccos, compared to the old charcoal fires, is really most marked, and the difficulty and danger of burning and over-firing is reduced to a minimum. One of the most nauseating duties of a tea planter must be tasting his different makes, and comparing them to those of other estates, who exchange with one another with this view. This business must be had enough for one who performs his work in London or elsewhere, but, for a man boxed up in the hot and close atmosphere of a factory, with the smell and fumes of tea constantly about him, it must be far from agreeable to wash one's palate out with rasping liquor, which nearly sets your teeth on edge even though one can gloat over the fine price likely to be realized hereafter in London. We tasted, amongst others, some Indian tea, and it was curious to note how much poorer in liquor it was to any of the numerous samples of Ceylon infused, whilst it also lacked, to some extent, the fine malty, and sugary bouquet which so distinguishes our teas.

HOT WATER FOR DESTROYING INSECTS.

BY ERNEST WALKER.

Hot water at a temperature of about 120° I find the most effective remedy I have ever tried for destroying insects on plants in the greenhouse. The plants may be either immersed in it, or the hot water may be applied with a plant-syringe, which is the more convenient of the two modes of applying it. If applied with a plant-syringe the water may be a few, say 10° hotter. While death to insects the hot water seems not to injure the plants in the least. I find one drenching of hot water with a plant-syringe has been sufficient to rid plants of red spider, where time after time cold water drenchings had been in vain.

At the last meeting of the Indiana Horticultural Society, in December, an extensive amateur fruit grower of this vicinity spoke of having used hot water—pouring a quart about the root of each tree—for the borer, which of course was done in early spring while the trees were yet dormant. In this manner he went over his young peach orchard of several thousand trees; and while the trees had previously suffered badly from the border, he never saw signs of them afterward.—*Gardeners' Monthly.*

WHAT IS A GUM.

In connection with the oft-repeated statement in the newspapers, that several of the important gums produced in Arabia and the Soudan, notably the gum-arabic, were greatly enhanced in price by the occurrence of the war, the interesting question arises, What is a gum? But little has been known regarding the formation of the remarkable exudations from certain trees called "gums." Quite recently it has been found, that by making an incision in the limb of a peach, apricot, plum, cherry, or other trees bearing stone fruits, and inserting a bit of the gum under the edge of the wound, an immediate formation of gum in copious quantity took place. These and other experiments lead to the belief that gums result from diseased action in trees, and that the disease can be set up by inoculation, just as small-pox is started in the human organization by similar means. Different diseases in different trees gives us dissimilar gums, as arabic, tragacanth and probably many resins and gum-resins. A flesh-wound on any part of the body forms an inlet for atmospheric bacteria, which produce inflammation, suppuration, and the outflow of pus: wounds on the trees allow of the ingress of peculiar bacteria, which produce tree-fever and the exudation of morbid matter called "gum." How strikingly alike are vegetable and animal growths!—*Popular Science News.*

INDIAN PHARMACOGNOSY.

At a time when utilitarian ideas exercise so dominating an influence as they do in the present day it may savour somewhat of the Quixotic to appear to advocate the extension of technical studies to antiquarian researches respecting drugs, since these do not, superficially at least, suggest yielding much of a *quid pro quo* in pocket or reputation. Many pharmacists are already disposed—and with good reason—to complain of the little value set by the public on qualifications obtained at the cost of hard labour and hard cash in order to enable them to serve it more efficiently. Certainly there is little in this direction to encourage the pharmaceutical student to stray beyond those bounds in the science of materia medica which enclose what is absolutely requisite in order that he may be able to pass his examinations and carry on his calling creditably. Yet there have always been a few who have interested themselves in points turning upon the history as well as the sources of drugs, and have been able to appreciate a work like 'Pharmacographia,' or a series of articles like the "Notes on Indian Drugs," from the pen of Dr. Dymock, which were published in this Journal a year or two since and were highly prized in many quarters, though they did not escape a somewhat irrational protest at home. It may interest some, therefore, to learn that the republication of the "Notes" by Dr. Dymock, systematically arranged and in a collected form, has been the occasion of the appearance of an appreciative article on Indian Pharmacognosy in the *Archiv der Pharmacie*, in which Professor Flückiger, who has himself made such important contributions to this class of literature, recalls some interesting facts in the antiquities of Indian drugs.

As late as the commencement of the sixteenth century very little comparatively was known in Europe respecting India. Although the importation of its products in the middle ages depended mainly upon the enterprise of the great commercial republics of Italy, even the most powerful of them had no direct and regular intercourse with India, and only occasional travellers from one or another of them reached the famous land. The notices of its drugs in those times were therefore few and widely separated. In the sixth century, Kormas, a Greek merchant and traveller, saw the pepper plant growing in its South Indian home and met there also sandalwood and cloves brought from the more remote east. In the ninth century, Kurdadbah, postmaster and minister of police to the caliphs of Mesopotamia, obtained certain information respecting camphor, cubebs, galanga, and pepper. A century later mention was again made of pepper by the Persian geographer Istachri, and in the twelfth century the first mention was made of cardamoms as an Indian drug by Idbisi, the Arabian geographer at the court of the Norman King Roger, at Palermo. The earliest information respecting Ceylon cinnamon dates from the thirteenth century. The fourteenth century saw members of different religious orders making their way into the peninsula, and from them came notices of ginger, and more information upon cinnamon and the important subject of pepper. But in the

first half of the fifteenth century a Venetian merchant, Niccoli de Conti, spent twenty-five years in India, and in his exhaustive and striking accounts of the spices and dyeing materials of Southern India went far beyond his predecessors, and may be said to have opened a new era.

In 1497, just as the Spaniards were invading a new world in the west, the doubling of the Cape of Good Hope by the Portuguese discoverer, Vasco da Gama, opened up a sea route to the East Indies, a feat which his countrymen were not slow to turn to advantage in establishing an important commerce. Amongst the officials sent over to look after the interests of Portugal was Thomas Pires, an apothecary, who was first appointed to the "factory" in Malacca, partially apparently in the interests of pharmacy, and afterwards was sent as an ambassador from Portugal to China. Writing from Cochin, in 1516, to King Manuel, he enumerates the drugs indigenous in the country, as well as those imported. The information contributed by this Portuguese pharmacist, though still too scanty, was an advance on what was known before. According to him frankincense came to Cochin from Arabia, as well as from Orissa, on the east coast of India, though what this latter frankincense was exactly is not now quite certain. Opium was imported from Egypt through Aden; but it was also already produced in Cambaya, north of Bengal, and Bombay. The drug was then only "eaten" (probably smoked) by kings and lords on account of the cost. Tamarinds, on the other hand, were so cheap as to be looked upon as a "vergelt's Gott." Pires also met there with aloes from Socotra, Aden, Cambaya, Valencia in Aragon and Sumatra. Among the "gomas fetidas" he enumerated sagapenum, galbanum and opopanax; but neither ammoniacum nor asafœtida. He also mentioned myrrh and liquid styrax. From the mineral kingdom, which was at that time well represented in pharmacy, Pires met with "tincar" (tincal) from Thibet and "rubine," as well as pearls from the Red Sea, Ceylon and Southern China. About the same time another Portuguese, Odoardo Barbosa, wrote an account of a journey through India, in which he quoted the prices of a series of drugs that he met with in Calicut on the Malabar coast. But a much more valuable contribution to the history of Indian drugs was made by a third Portuguese, Garcia de Orta, who in 1534 went out as physician on board an admiral's vessel and settled down at Goa as royal physican to the hospital. There he produced his famous 'Coloquios dos Simples e Drogas,' in which Indian drugs were described with a care previously unknown, the descriptions being accompanied by a mass of other useful information. Next to that of Garcia the name most worthy of mention in connection with the history of drugs in the sixteenth century is Filippo Sassetti, who writing to a friend in his native state of Florence, probably from Cochin, discoursed right intelligently of the catechu tree (*Acacia Catechu*) and Ceylon cinnamon bark. In the next century the Dutch became powerful competitors with the Portuguese for the commerce of these regions, and wrested from them successively the famous Spice Islands or Moluccass and Cochin. Some knowledge of the natural products of the neighbouring countries must therefore have become a desideratum to the new masters, and it was in these circumstances that Hendrick Adrian Rheede tot Drakenstein, the Dutch Governor of the Malabar Coast, ordered the compilation of the 'Hortus Indicus Malabaricus,' which was not published however until 1703, four years after his death. In this work, which consisted of twelve folio volumes and was illustrated by seven hundred and fifty plates, many of the medicinal plants of Southern India were figured and described. Another contribution to this field of literature from Holland was Burman's 'Thesaurus Zeylanicus.' After the British rule had become definitely established in India, especially by the memorable battle of Plassey, in 1757, the ground was taken up by investigators from our own country, Dr. William Roxburgh being in the front rank. In his 'Plants of the Coast of Coromandel,' published in the years from 1795 to 1819, and his 'Flora Indica,' published between 1820 and 1832, not a few plants of pharmaceutical or technical interest were figured and satisfactorily described for the first time. In 1813 another English physician, Dr. W. Ainslie, in his 'Materia Medica of Hindostan' called attention exhaustively to the popular remedies of India, a subject which had been, partially dealt with three years before by Fleming in a 'Catalogue of Indian Medicina] Plants and Drugs.' Then followed a number of valuable botanical works, in which, however, pharmacognosy had no special place; among these may be mentioned Wallich's 'Plantæ Asiaticæ Rariores,' Wight's inclusive but artistically unimportant 'Illustrations of Indian Botany' and 'Icones Plantarum Indiæ Orientalis,' and Royle's 'Illustrations of the Botany and other Branches of Natural History of the Himalayan Mountains and of the Flora of Cashmere.' In 1837 this last-mentioned author, who was a medical man in the service of the East India Company, broke fresh ground in the still imperfectly worked field of Indian medicine and published an essay on 'The Antiquity of Hindoo Medicine,' a line that has been followed in more recent years in Udo Chand Dutt's 'Materia Medica of the Hindoos.' In 1842 a new phase in the literature of Indian materia medica was initiated by the issue in Calcutta, by the order of Government, of O'Shaughnessy's 'Bengal Dictionary,' which was but the forerunner of the 'Pharmacopœia of India,' a work prepared under the authority of Her Majesty's Secretary of State by Dr. Waring, assisted by a Committee of native and English experts, amongst whom was the late Daniel Hanbury. We have thus followed Professor Flückiger through his *résumé*, dating from the earlier notices of separate Indian drugs to a period when they were first officially catalogued and described in a national pharmacopœia. Here we must leave him, notwithstanding that a flattering mention of the place which this Journal has taken in this field of literature might have excused our pursuing the subject a little further.—*Pharmaceutical Journal.*

WOOD ASHES.—The best results from wood ashes are secured by adding a small proportion of common salt. Ashes contain all the mineral elements of the plant, and they exert a good influence in unlocking fertility that would not be otherwise available. In burning anything the chlorine it contains is carried off with the smoke, and salt, chloride of sodium, supplies the deficiency.—*Coleman's Rural World*

DEAD LIMB EVAPORATION.—"A. J. M." writes:—"While a dead limb may be injurious, I do not believe it transpires moisture as fast as a green one in leaf, and if the moisture was excessive, its evaporation would be beneficial. Where can we find the facts and figures of this evaporation?" [A dead limb can scarcely be said to transpire, which is a term wholly applied to the action of a being with life. Moisture simply evaporates from a dry stick, and by the power of capillary attraction, as fast as it dries, it will absorb moisture from any thing to which it may be attached that is moister than itself.—ED. G. M.]—*Gardeners' Monthly.*

POLLINATION OF EUCALYPTS.—On this interesting subject, which was discussed in these columns some time since, Baron Von Mueller writes:—"The pollen is shed on the stigmas of Eucalypts before the operculum drops; but of course honey-seeking insects may occasionally carry additional pollen form other flowers and even other species, the fruit being polyspermous. Natural hybrids among Eucalypts are probably rare—at least I do not find transitory forms among the several gregarious species of any one locality, but artificial impregnation would not be difficult. Crossing of the large-flowered species, particularly those having red and yellow filaments, with each other, would doubtless produce new horticultural forms, some likely to surpass in beauty the natural ones."—*Gardeners' Chronicle.*

A NEW VINE DISEASE IN SOUTH AFRICA.—A new and formidable Vine-plague is reported from the Cape. A correspondent, writing from Robertson to the *Cape Times*, says (according to the *Colonies and India*), "On a farm recently visited by him two hard-working young fellows had planted last year a piece of new vineyard with some 20,000 Vine-stocks. The ground being well trenched, and the soil rich, the result of their labour proved most satisfactory until very recently, when a strange beetle made its appearance in the vineyard. The insect attacked the Vines first below the soil, biting off the bark all round the Vine-stick, thus stopping the sap from rising upwards, and thereby destroying the Vine. In less than a week more than half the Vines died from the attacks of this pest. Dr. Hahn was immediately communicated with, and went at once to inspect the Vines. He declared the beetle to be an insect known in Italy, where it frequently attacks and destroys vineyards, as the Vine-leaf Beetle." What is this?—*Gardeners' Chronicle.*

FLORIDA PER CONTRA.

TO THE EDITOR OF THE "FIELD."

SIR,—In your paper of March 15 I see a letter under the above head, which it would be hardly worth while to notice, were it not that it might mislead some people who read it hurriedly. Here are some of the statements:—"Orange groves, for instance, take an immense time to really pay." Who but a child, or a grown person talking to children, would find it necessary to explain that orange trees do not bear and "really pay" the first year they are planted—that they are not cereals, in fact? Who else would find it incumbent to make the statement that "Lemons, besides taking time to bear, want a lot of knowledge as to proper time of picking." That lemon trees take time to bear is so obvious as to be hardly worth insisting upon, but that they also "want a lot of knowledge" on any subject requires proof. "Citrons cannot pay unless there is a factory near for the peel." It might as well be said that citrons cannot pay if you leave them to fall and rot on the ground. "Pomeloes and shaddocks do not seem to be in much demand." Oddly enough, this is to some extent the case with crab-apples in England and wild mangoes in India. It is incorrect to say that this year all tropical plants were killed by frost in the neighbourhood of Leesburg. I myself have many tropical plants which have survived the winter. Fever and ague and dysentery are, and always will be, common enough no doubt in a semi-tropical or tropical country, amongst those people who choose to reside on the borders of swamps and live on bad food, bad water, and worse whiskey. No one is obliged to run this risk any more than he is obliged to buy "rotten furniture" or "clothes unsuited to the climate." That each and all these things are done is not the fault of Florida. Your correspondent states that yellow fever is at all times ready to break out in Florida, even in the interior. As it never has broken out in the interior, one is at a loss to understand how he arrives at this conclusion. I have had some experience of yellow fever in the West Indies, and, as everyone knows, it is carried from one seaport to another; but in each the most careful quarantine regulations are in force, and I for one never heard of an instance of yellow fever breaking out in the interior of any country. I make no *couleur-de-rose* statements with regard to Florida. It is enough to tell any thinking man that the winter climate here is delightfully perfect, and that it is within two or three days' journey of New York and many other northern cities, the winter climate of which is detestable; that an orange grove costs a little money and a good deal of time, or a good deal of money and no time to acquire, and when acquired is a good and sound investment. If he believes this much only, he must see that the future of Florida rests on a solid basis, and that it must become a very thriving State in the near future.—C. NUTCOMBE GOULD, Zephyr Lake, Leesburg, Sumter Co., Florida, U. S. A., April 9.

CHARDUAR RUBBER PLANTATION IN ASSAM.

On the 21st February last, Mr. Gustav Mann, Conservator of Forests, Assam, submitted to the Chief Commissioner a report on the Charduar rubber plantation in the District of Darrang, including its past history, the results gained, and a sketch of his views as to the future treatment and extension of that plantation. The following extracts are interesting:—The total area of the Charduar caoutchouc plantation is now 892 acres, and has cost R64,351 or R72 per acre. This is abnormally high, since much of the work during the first five years had to be done twice over, and sometimes oftener, because the planting of caoutchouc trees was new, and everything had to be learned and found out by experiments, which naturally took some time. But matters have changed in this respect. We know now what we are about, and the officer in charge of this work, Mr. T. J. Campbell, has estimated the cost of the extension which is at present being carried out at R29 per acre, to which another R6 for subsequent cultivation and clearing should be added, bringing the cost, including everything, up to R35 per acre.

Besides the experimental nature of the work, to which the cost of R72 per acre of this plantation must to a great extent be attributed, we have also prepared extensive nurseries, covering an area of about 23 acres, and containing some 184,000 plants of different sizes, which is sufficient to extend the plantation by 200 acres per annum for the next 15 years, or a square mile per annum for the next 5 years, if desired, and these nurseries have been so planted that, if for special reasons it is considered advisable not to extend the plantation at any particular time, the trees can be kept almost stationary for 15 to 20 years without becoming less suited for transplanting—a particular advantage enjoyed by *Ficus elastica* in common with other semi-epiphytes as compared with ordinary trees. To make an even approximately correct estimate of the probable revenue that may be expected from these plantations, it is first and foremost necessary to know what a rubber tree will yield, and on this point our information is most imperfect. The statements made by rubber collectors are quite unreliable, and the exhausted state of the naturally grown rubber trees has prevented us until last year from making experiments; the result of last year's experimental tapping, as recorded in Appendix IX of last Annual Forest Report (1882-83), interesting as it is, and much as it has increased our knowledge of the yield of caoutchouc from *Ficus elastica* still leaves us in considerable doubt on the subject, as has been stated in paragraph 118 of that Report. However, so much is certain, that a full grown rubber tree of about 50 years old will yield at the very lowest 5 seers of rubber, if very carefully tapped, and this quantity may be expected about sixteen times, which will be an equally safe estimate for calculating the yield of a rubber tree. To be quite on the safe side, I will only calculate ten trees per acre, which would give us about 20 maunds of rubber from every acre. This, at the price at which rubber was collected last year in the Darrang District and sold, and deducting the expenditure incurred on collecting it, would give us a net profit of R54 per maund, or R1,080 per acre in 50 years, and if the rubber trees have a longer life, the yield may be reckoned for their remaining years of life at the same, if not at a higher rate. An acre of first-class timber trees would cost about double as much to plant and maintain at the rate of 60 trees per acre; and taking the value of the trees at R10 each (the present royalty charged), this would give us R600 only, as compared with R1,080 from rubber, and most of the first-class timber-trees will require 100 years to reach maturity, or double the time of a rubber tree. This means, in other words, especially if the compound interest on the capital used is taken into consideration, that an acre planted with rubber-trees will give about four times as much revenue as an acre planted with first-class timber trees. It may be, and in fact has been, argued that rubber might be produced artificially, and that thus a fall in the price might be brought about. I think there is little to be feared in this respect, not more so than timber has to fear from the extended use of iron; and rubber, being a raw product, has a great advantage, inasmuch as the artificially-produced article would have all the cost of manufacture added to the cost of the raw materials, and I myself have not the slightest fear in this respect. The price of rubber has been very high for many years now, and during this time it is known that effort have been made to produce artificial rubber, but that they have failed. It now only remains for me to consider the value of *Ficus elastica* as compared with other trees yielding rubber both as regards quality and quantity, and although it must be admitted that the rubber yielded by our indigenous tree is slightly inferior to that from some other rubber trees, the difference is so little that in my opinion it has nothing to fear in this respect, and as to the quantity yielded by other species we have positively no authentic information to make comparison; but am very doubtful whether any of them will yield more than *Ficus elastica*, and certainly the difference, if any, could not be so much as to make the cultivation of the latter unadvisable.—*Madras Mail.*

DISCLOSED FROM THE QUININE MARKET.

In consequence of the rupture of the union of all the most eminent quinine manufactures of the world, which occurred in January last, the price of this medicine has greatly declined, and it may be supposed that, unless said manufacturers come to a new agreement, it will shortly go down considerably lower. The first reduction of the price

was made on the 24th January, it being a diminution of 80s per ounce, so that at present an ounce of quinine costs only M. 6·40 instead of the former M. 7·20.

Altogether there are but 17 quinine factories in the world, that are making to any extent, and they are distributed throughout the world as follows:—In Germany there are six, in Italy two, in France three, in England two, and in the United States of North America four. The German manufacturers are as follows:—Friedrich Jobst, Stuttgart, C. F. Böhringer & Söhne, Mannheim, Conrad Zimmer, Frankfort on the M., Rostock & Co., Leipsic, Brunswick Quinine Factory, Brunswick, F. Koch, Oppenheim on the Rh., Quinine Factory Auerbach, Auerbach, Hesse. The Milan factory is that of Alexander Böhringer, the English, Howard & Sons, and Whiffen & Co., the Parisian Armet de Lisle & Co., their American competitors are Messrs. Kesson & Robbins, New York, Powers & Weighmann, Rosengarten & Sons, and Kesby & Missar, Philadelphia.

The annual produce of all the quinine factories in the world combined, is estimated at 4,250,000 ounces, of which America alone consumes 1,700,000 of quinine each year, whereas it produces but 850,000 ounces per annum, a quantity which of course is not exported, but, on account of its fine quality, remains and is consumed in the land. It is left to Europe to supply the larger part of the consumption, which therefore has it in its power to control the market and regulate the prices, which for many years were subject to but trifling fluctuations.

If in the course of any year an overproduction resulted, the manufacturers came to a mutual understanding in stipulating and keeping up the price of quinine. Again in July last the thirteen European quinine factories came to such an agreement, binding themselves under penalty to sell their fabrics only at the price agreed upon.

The proprietor of one of the most considerable quinine factories in the world, Mr. Alexander Böhringer of Milan thereupon undertook to induce the American colleagues to join this union, and for this purpose undertook a voyage to the United States, where about the time Congress had accepted a bill for abolishing the duty on quinine, and thus giving cause for the American quinine manufacturers to tear the European competition as soon as the Continental stocks, that could not be realised at home, should be thrown into the American market. Mr. Böhringer's proposals consequently met everywhere with a hearty reception, nay, the American colleagues submitted to him even more advantageous proposals, agreeing and obliging themselves to take to account a certain percentage of the annual European produce.

Thus all competition was paralysed by the world-union of quinine manufacture. The agreement should be valid for a period of three years, and could be dissolved only by mutual consent.

Scarcely, however, had Böhringer returned to Europe, and announced the success of his exertions, when several European colleagues broke the given promise and began to sell their fabrics far below the prices agreed upon. In course of the year the demand for quinine proved to be rather dull, and some of the less wealthy manufacturers, thinking to see their subsistence endangered, felt themselves compelled to break the contract.

The consequence of this was that the American colleagues freed themselves from the compact, whereupon the goods were sold as any, even ruinous prices. While during the last six years the price of quinine had been held at M. 6 per ounce, and for very superior articles had risen even to M. 23, it now suddenly went down to M. 6·40 per ounce. The lowest price ever fixed for quinine, is that paid about twenty years ago, when the firm of Powers & Weighmann in Philadelphia, the largest American quinine concern, would oppose a powerful competition to the enterprise of Messrs. Armet de Lisle & Co., who had opened a second factory at Haarlem, and reduced the price of quinine to M. 4·04 per ounce, by which they immediately stopped the working of the newly created factory. When, however, Armet de Lisle & Co. desisted from their plan, the price soon went up again.

For quinine in bottles the present wholesale price is fixed at M. 6·40 per ounce, and in lumps only M. 6. On the retail trade this fluctuation has no influence, for with small stocks a regular demand continues, and therefore the public in general have no advantage of it. The rupture of the union led to a London syndicate's buying up about 30,000 ounces of quinine, by which Messrs. Howard & Sons were induced to reduce their prices in order to frustrate and meet the syndicate speculation. The large stock could not now be realised at M. 6 per ounce, and was finally cleared off at a great loss.

There is no saying with any certainty what course the matter will now take, but the fact of the great discord among the quinine manufacturers is still evident, and the consequent unsteadiness in the prices. The market is quiet, buyers being very reserved in laying new stocks in the apprehension of further reductions in the prices. Should a union of the quinion manufacturers be re-established, for which purpose introductory steps are reported to have already been taken, buyers will have to pay dearly for their reserve from the rapid rising of the prices. Consequently all the parties concerned are looking forward to the next meeting with great suspense.—*Exporter.*

MANURES.

SEA MUD AS A MANURE.

At the mouths of most rivers there is a deposit of mud which it is to the advantage of harbor authorities to remove and of farmers to utilise. Several German chemists have recently examined various samples, and find that the composition is very uniform, the only substance which varies much in quantity being sand. Exposed to the air the mud dries up to a firm, compact mass, losing water and diminishing in volume. Long storage brings about changes of considerable importance from an agricultural point of view, for the mud becomes more powdery, especially after frost, and is then more easily incorporated with the soil; the loss of water and the reduction in volume diminish the expenses of transport; chlorides are lost, the oxide and sulphide of iron get oxidised, organic remains in the mud become more decomposed, while but little, if any, nitrogen is lost. Such sea mud is, therefore, well worth the attention of farmers near the mouths of rivers, as, after drying, it is capable of effecting a desirable physical change in the soil, as well as of improving it chemically by adding to it nitrogen, lime and soluble sulphate.

MANURIAL VALUE OF SEWER SLUDGE.

Among the plans proposed, or in use, for the disposal of town sewage is one whereby the liquid and solid materials are separated gradually from each other. Alum water is mixed with the sewage as it flows from the main drain over a series of precipitation tanks. The solution of alum assists the coagulation of the solid part of the sewage, which is slowly deposited in the tanks, and, in the end, the water becomes quite clear, contains only a trace of nitrogen, and may be safely turned out into an adjacent stream or river. This plan is in practice at Coventry, Leyton, West Ham and other places, and is the one proposed for the towns in the Thames Valley Confederation. The chief difficulty is the disposal of the sludge which remains in the tanks. By powerful presses its bulk can be much reduced, and this would also lessen the cost of transport. It was hoped that its manurial value would render it a marketable article, but analysis shows that as a manure it is worth very little. These remarks have been suggested by an account of analysis of sewers lime made at the town of Bremen. Several house sewers, containing much urine, are led into a small stream with a gentle fall; the solids are deposited, and are used for dressing soils. The dry solids contained per cent of potash, 6·3; lime 17·2; phosphoric acid, 8; total nitrogen, 11·6. The wet material exposed in heaps to the air loses 40 or 50 per cent of water in drying, and it requires a long exposure to get the sulphur compounds oxidised. The reason the liquid part of ordinary town sewage contains so little nitrogen, is that it is so enormously diluted with all the water used for domestic purposes in houses, and with all the rain that falls in the town.

PHYSICAL EFFECTS OF MANURES.

It too frequently happens that in considering the effect of a manure its chemical action on the soil is alone thought of; besides this, however, its mechanical action should also be taken into account. It is, as we have previously maintained in these columns, very much to its influence on

the physical properties of the soil that the universally good results following the application of farmyard manure are to be attributed. Wollny has made some experiments with artificial fertilisers which are worth notice. He mixed clay thoroughly with water, so that the liquid was crowded with innumerable fine particles of the earth. On adding small quantities of ammonia, or of alkaline phosphates or carbonates, to the water the clay is at once precipitated in a dense form. On the other hand, mineral acids and their salts, such as nitrate of soda, act in the opposite way, precipitating the clay, it is true, but in a light and spongy form, occupying much space. Hence he concludes that the addition of alkaline substances to soils has an unfavorable effect on their porosity had lightness, and consequently on their fertility; and he quotes, as cases in point, the alkali plains of Nevada and California, the soil of which is hard, dense non-porous, and sterile. On the other hand, such salts as nitrate of soda, sulphate of potash, saltpetre, and kainit produce at once a beneficial effect on the porous character of arable soil; but the salts mentioned are so quickly washed out in case of rain that the effect is not lasting. Of all artificial fertilisers it is found that lime exercises the most favorable influence on the physical properties of the soil, causing it to aggregate into floculent particles which persist for years, thus making it light, and therefore more fertile.

MANURIAL VALUE OF DRIED BLOOD.

A. Petermann's analyses of thirty-two samples of dried blood gave an average of 11·23 per cent of nitrogen; the physical condition was dry, friable and almost free from smell. To determine the manurial value, plants were grown in pots on two kinds of soil of very different character. On each kind of soil plants were grown with no manure, with blood refuse, and with nitrate of soda, containing nitrogen equivalent to that in the dried blood. The soils consisted in the one case of a loam, in the other of sand. Fifteen pots of each were used, and 10 grains of spring wheat sown in each pot on the 17th March. On the 20th August the plants were removed from the pots, and the straw and grain weighed separately. The tabulated results show that the loam gave the highest yields, but the effect of the manures was greatest on the sand; in other words, the difference between yields on unmanured and manured sand was greater than between the corresponding loams. In the loam, dried blood produces an increase in the crop practically identical with that given by a quantity of nitrate of soda containing the same amount of nitrogen; the further addition of phosphoric acid or potash, or both, has apparently little effect. In the sand, dried blood is decidedly inferior to its equivalent of nitrate of soda, and both phosphoric acid and potash produce considerable effect; that of the phosphatic manure, in all the cases in which it was employed, being to hasten the period of ripening. From the results of these and previous experiments the nitrogenous manures which have been tried have been arranged in the following order of efficiency, the best being placed first:—Nitrate of soda, dried blood, dissolved wool, wool refuse, leather refuse. The greater the solubility or the readiness to undergo decomposition, the greater the efficiency.

MANURE FOR BEET ROOT.

It has recently been again suggested that the beet should be grown in this country as food for stock. The best manure for the full production of sugar in the beet is, according to Holdefleiss, a moderate application of stable manure, supplemented by Chili saltpetre (nitrate of soda). Manures that are too rich in nitrogen, such as sheep dung, are decidedly injurious, as is also too free an application of Chili saltpetre. If stable manure is not conveniently obtainable, a mixture of superphosphate with the saltpetre is recommended.

MANURING EXPERIMENTS WITH RYE AND WHEAT.

These have been made by Marcker in the case of rye, on a good sandy soil, to test the effects of phosphoric acid in bone meal and in purely mineral phosphates, blood meal being added to the latter, and containing as much nitrogen as the bone meal. Five farmers worked independently of each other, and the results came out slightly in favor of the mineral phosphates with blood meal. On light, poor sandy soils the steamed and fermented bone meal gave the best crops. Some plots of wheat were dressed with Chili saltpetre, others with sulphate of ammonia. They were applied at different periods, and the saltpetre was found greatly superior, the yield in both grain and straw being considerably larger than on other plots.

ARTIFICIAL MANURES AND POTATOES.

Guradze records results of five experiments on the effects of various chemical manures on the growth of potatoes. The manures were a newly introduced potash-magnesia (containing 50 per cent sulphate of potash and 34 per cent sulphate of magnesia), superphosphate and Chili saltpetre. The plots received in addition to the artificials a considerable quantity of stable manure. All the crops were exceptionally good, and the plants healthy: the tubers held a good proportion of starch, and the value of the increased production repaid the cost of the extra outlay on manures. The use of artificial fertilisers in growing potatoes is strongly recommended by the experimenter.—*Mark-lane Express.*

THE COCANADA OIL INDUSTRY.

A gentleman residing in the locality writes to us:—

We learn from the Official Review of the Maritime Trade of British India for 1881-82 that, out of a total export of 3,009,288 gallons of castor oil, 2,627,923 gallons were shipped from Calcutta. Bengal has, therefore, practically the whole trade in castor oil, though the seed from which the oil is obtained is largely imported to that Province from the Madras Presidency. The quantity of castor oil exported in 1877-78 was 1,411,216 gallons, so that the increase in the five years ending 1881-82 has been nearly 113 per cent! But the corresponding figures for the export of the oil seed is something marvellous—an increase of 55 fold—from 4,521 cwt. in 1877-78 to 250,696 cwt. in 1881-82! These large increments have been variously explained. We agree with the view that they are in a great measure due to the continued expansion of the importations of mineral oil, which has now largely displaced castor oil amongst the natives. This account of the matter is supported by the fact of the fall in the prices of both the oil and the seed, when compared with those of previous years. The reduction in price is specially noticeable from a comparison of the Trade Returns of 1880-81 and 1881-82. We there find that while the exports of castor oil for the latter year exceed those of the former by 118,485 gallons, their total value was less by R1,27,579. Similarly, with castor seed for the same periods, the shipments show the large increase of 228 per cent in quantity, but only 171 per cent in value. These marked differences cannot, however, be wholly due to the extended use in the country of the cheap, foreign illuminating agent, *Kerosine.* For it must be remembered that the demand for castor oil on the Indian Railways—both for lighting and lubricating—has risen manyfold in recent years. "Increased production" must therefore be a factor in the increasing exportation of oil and seed as well as in the rapid decline in their average prices. It is interesting to note that the export of oil-cake is not in proportion to that of oil, being much below what might be expected from the increased exportation of oil. This shows that the advantages of using this article are coming to be understood and appreciated by the Indian ryot, who is wise in utilising a waste product for the enrichment of his own lands, and in not allowing it to go, as heretofore, to benefit in like respect the Colonial Planter, who was by this means enabled to out rival him in other products. The heavy reduction in the price of this article from R50 in 1880-81 to R40 in 1881-82 per ton may be ascribed to the falling-off in the demand from Ceylon; because Brazilian coffee is taking the place of the Ceylon berry in the markets of the West. The demand, however, from the sugar planters of Mauritius and the Straits of Java still continues brisk, and the West Indies, *via* the United Kingdom, bid fair to become our best customers.

The foreign export of castor oil from the Madras Presidency (which has 67,000 acres under this crop), in 1881-82 was 205,274 gallons, and that of seed 172,536 cwt. And as no inconsiderable portion of these quantities are contributed by the Godavery District, besides its enormous seed shipments to Calcutta from Cocanada, a few words relative to the oil-mill industry in the latter locality may not be devoid of interest or unacceptable to our readers.

The factory at which our information was procured is the eldest in this part of India, and possibly, the pioneer oil-mill of the whole country. It is situate in the old Dutch settlement of Jaganadapuram, which forms the southern portion of the present town and port of Cocanada. This establishment was opened in 1854 under the auspices of the well-known name of "Burgomaster," and, subsequently changing hands, passed to its present proprietary—the well-known and far-famed Pyda Ramakristniah, otherwise called the apostle of Hindu-widow-remarriage. The *modus operandi* of the cold-drawn process of making castor oil, as carried out here, may be distributed under the following sub-divisions of labor:—

1.—*Shifting*, or the freeing of the fresh seed from dirt and impurities as a preliminary to manipulation.

2.—*Husking*, in which the seed is partially crushed, so as to loosen the shell from the kernel.

3.—*Winnowing*, or the separation of these latter.

4.—*Flowering*, in which the kernels are crushed or bruised sufficiently for disintegration.

5.—*Drying*, to granulate, as it were, the broken product.

6.—*Bagging*, or equally and uniformly encasing the thus prepared kernel in gunny wrappers of a suitable size for the press.

7.—*Milling*, in which the oil is expressed by machinery, from these canvas covered packages or "bricks," and the exuding product collected.

8.—*Boiling*, or the first operation in refining.

9.—*Filtering*, or the final process of purification before storage in cistern or vat.

10.—*Canning* or *Barrelling* for expert.

Thus husking (2) and flowering (4) are effected by ordinary hopper machines, with horizontal rollers worked by hand (3 men), the combined operations costing 3 dubs or 9 pies per bag.

The winnowing (3) is cheaply done by women and children. The proportion of husk to seed is one-fourth—that is, about 41 lb. of refuse per bag of 164 lb. of castor seed. There is no waste, as this refuse furnishes much of the fuel used in boiling (8).

The drying (5) is a simple process, being carried out on a chunam terrace or platform, within the precincts of the establishment.

The bagging (6) is done at the oil press by the press-men. The powdered kernel is hand-squeezed and beaten into "bricks," measuring 12 in. by 6 in. by 2 in., and enclosed in gunny strips expressly cut for the purpose.

The milling (7) or the extraction of the oil by pressing-machinery is the most important of all the operations here described. The appliance is the common press, with vertical plates, used generally for seed oils, worked by hand power. The quantity that may be obtained each day of 10 hours from each press is about 305 lb. of oil. Each machine can press (164—41) 123 lb. of "kernel-flower" every 2 hours; and, as 50 per cent is the proportion of oil derived, the result of five relays is, omitting fractions, 5 times the half of 123 lb., or the figure mentioned (305 lb). The labor employed is 4 men per machine per diem, who are paid on the outturn at the rate of R2-4-0 per candy of 500 lb. of unrefined oil, so that their daily earnings come to 6 annas each—apparently high wages, but by no means so when the hard and trying nature of the work is duly weighed and valued.

Boiling (8), which might be considered the simplest of the operations, demands the exercise of the greatest care, together with some degree of skill. To a gallon of unrefined oil, a pint of water is added, and the mixture is boiled in iron pans till the water is evaporated. The principle of this process is embodied in the fact that, in the cauldron the mucilage should encrust and the albumen coagulate, and measures are therefore taken to regulate the temperature accordingly. Otherwise, the resultant will be an inferior product in color, odour, and flavour. When this operation is carried out on a large scale, it requires but a small addition of other fuel to the refuse (husk), which is always available to keep the fires going. This makes the expenditure under this head comparatively very small, involving little more than the cost of the necessary attendance. Each oil-pan has a capacity of 350 lb. They are of local manufacture, and are said to cost R62 each. The sediment remaining after the boiling is completed and oil taken off is sometimes re-milled.

Then comes the final operation of filtering (9) through coarse cloth, while the pure oil is let run into tanks, and is thereafter known as COLD DRAWN CASTOR OIL.

The method of canning or barrelling (10) is that followed in the case of other seed-oils. The tins are of the usual kerosine size, holding from 40 to 43 lb. of oil. When filled they are put into wooden cases—4 tins to a box. The tins are locally made, and sold at from 7 as. to 8 as. each; while boxes, made of country wood, cost a rupee a piece. The empty cask is said to cost from R7 to R7-8; and as it is capable of holding 500 lb. of oil, more or less, the saving in casking over canning is something like R2-8-0 per candy. But this saving is at the expense of purity, for the oil degenerates when kept in wood.

The weekly slip of quotations issued by the Cocanada Chamber of Commerce on the 21st March last showed that castor seed stood at R6-1-0 per bag of 164 lb. net, packed in Bengal gunnies; and castor oil in cases at R61-0-0 per candy of 500 lb.

Although these figures represent export value free on board, they may enable us to arrive at the cost of production with the probable value of the benefit to be derived therefrom.

It takes 8 bags of seed to yield one candy of oil, so that R48-8-0 represents the first outlay, to which R9-0-0 should be added for tins and cases; R2-4-0 for pressing; R0-6-0 for husking and crushing; R0-4-0 for boiling, sifting, etc. These give a total of R60-6-0 which, when taken from R61-0-0 leaves only as. 10-0 to profit. This figure has, however, to be increased by the value of the eight empty bags, R2-0-0; and the price of one candy of punnock (oil-cake), say, R9-0-0; which items raise the margin of gain to R4-10-0 per candy. When a portion of this sum is written off for stock, superintendence and contingencies, the residual difference will go far to prove that there might be less remunerative industries than castor oil manufacture. —*Madras Times.*

AQUEOUS EXTRACTION OF CINCHONA BARK.*

BY PROFESSOR REDWOOD.

Among the various forms that have been devised for the administration of cinchona bark, preparations produced by aqueous extraction have always occupied a prominent position. Even since the discovery of the alkaloids, which are the only powerfully active therapeutic constituents of the bark, medical men have not been always satisfied with the use of these to the exclusion of other constituents, and therefore tincture, infusion, decoction, and fluid extract, are preparations which have been frequently employed, and from the use of which effects have resulted which the alkaloids alone have failed to produce. Where water alone is used for extracting medicinal properties from bark, as in the three last named preparations, there is a strong ground of objection to the mode of operating officially authorized in those cases, which is that a great part of the most valuable constituents of the bark operated upon is left in the marc, the menstruum used being incapable of dissolving them, and holding them in solution. This result with reference especially to *Extractum cinchonæ liquidum* of the British Pharmacopœia, has called forth a good deal of criticism when that preparation has come under discussion; but the defects which have been pointed out and commented upon, as indicated by analyses made both of commercial samples and of samples specially prepared for the purpose, may, in several, and in all the most glaring instances, be ascribed in great part to faults other than those which essentially appertain to the process. It cannot, however, be contended that the process is a good and satisfactory one. Some of our best practical pharmacists have for some time past been seeking, or having found have been applying, processes which are said to yield better results, but unfortunately we have no published account of the investigations which have led to those results.

I have on several occasions endeavoured to induce some of my pharmaceutical friends to undertake the investigation of the best mode of preparing *liquid extract of cinchona*, with a view to publication; but, not having succeeded in that direction, I have made some experiments

* Read at an Evening Meeting of the Pharmaceutical Society, April 2, 1884.

myself, for the purpose of testing the feasibility of obtaining aqueous extracts of cinchona better suited for use in medicine than those which are at present official.

I started with a decided opinion, founded on previous observations, as to the direction in which the investigation should be pursued, and the objects which it was most important to accomplish. They may be stated as follows:—

1. That the red or succirubra bark is the sort most suitable for use in these operations.

2. That the extracting liquid should be water, an acid being used to render the active medicinal constituents of the bark soluble in this menstruum.

3. That the bark should be exhausted of its alkaloids in the process adopted, and that the extract should contain such other constituents of the bark as are considered to be medicinally valuable.

4. That the liquid extract should contain a specified quantity, say 5 per cent, of the mixed alkaloids of the bark.

5. That the liquid extract should admit of dilution with water without becoming turbid, and, on the other hand, that it might be evaporated to dryness without impairing its solubility to any appreciable extent.

In view of the numerous discussions that have taken place from time to time with reference to the selection and treatment of cinchona bark in its preparation for use in medicine, it will not, I think, be considered necessary that I should enter here into a detailed representation of the advantages resulting from the accomplishment of the foregoing objects. I will therefore at once describe the process I have adopted, by which those objects appear to be completely, easily, and economically carried into effect.

Extract of Red Cinchona.

Take of—

Red cinchona bark, in No. 50 powder.....	1 pound.
Distilled water.....	4 pints.
Hydrochloric acid	½ fluid ounce.

Mix and macerate at a temperature of 180° F. for four hours, stirring frequently, and replacing the water that evaporates. Allow the mixture to cool; then transfer it to a percolator, and when the liquid ceases to pass, carefully introduce distilled water over the surface of the solid matter in the percolator, and continue to percolate slowly until ten pints of liquid have passed, or it is found that what is passing has ceased to give a precipitate on the addition to it of an excess of *liquor sodæ*.

Evaporate the percolated liquid, at the heat of a water-bath, until it is reduced to one pint. Let it cool, then add three pints of distilled water; stir them together while a precipitate is forming; separate the precipitate by filtration; well wash the filter and its contents with distilled water; evaporate the whole of the filtered liquid at a temperature not exceeding 180° F. until it has acquired a syrupy consistence, and dry this either in thin laminæ on the surface of glass, or in thicker masses by exposing it in shallow dishes in a drying closet.

Dissolve 20 grains of this extract in a fluid ounce of distilled water and add three fluid drachms of *liquor sodæ*. Mix thoroughly and let it stand for twelve hours that the precipitate may subside. Collect the precipitate on a filter, wash it first with distilled water rendered alkaline with *liquor sodæ*, and, finally with water alone, and when it has drained transfer it to a dish and dry it at 212 F. Its weight multiplied by five will represent the percentage of total alkaloids in the extract.

Take of *Liquid Extract of Red Cinchona.*

Extract of red cinchona, as much as contains of total alkaloids	437·5 grains.
Distilled water	A sufficiency.
Rectified spirit.....	5 fluid ounces.

Dissolve the extract with the aid of a gentle heat in twelve ounces of the water, when cold add the spirit, make up the volume to 20 fluid ounces by further addition of water, and filter.

The principal object in this process has been the production of a liquid extract of known and uniform alkaloidal strength, which, while it possesses the aromatic flavour and astringency of the bark, is free from much inert matter, and from the peculiar extractive (chiefly quinovin) which, in our official liquid extract, forms a dense, unsightly and disagreeable precipitate when diluted with water.

Hitherto it has been the practice to prepare the liquid extract so that it shall bear a definite relation in volume to the weight of the bark from which it has been made; but as it is practically impossible to ensure uniformity of composition or of alkaloidal strength in the samples of bark employed, the properties of the prepared extract have necessarily differed as widely as those of the barks from which they have been obtained.

The mode of proceeding in this process admits of the use of any but the lowest qualities of the red barks of commerce. The total alkaloids contained in the dry extract produced in the first stage of the process are easily estimated, and the percentage of alkaloids being determined, while the extract is soluble in water, there will be no difficulty in ensuring uniformity of strength in the liquid extract. By the process as given it will contain 5 per cent of mixed alkaloids in addition to the other constituents of the bark that are left in it. Thus a fluid ounce of the liquid extract may be considered to contain all the valuable medicinal properties of an ounce of red cinchona bark of good average quality.

It is obvious that the result indicated could not be obtained without using an acid in addition to that present in the bark, and there is no evidence that I am aware of to show that by causing alkaloids which would otherwise be wasted to combine with 9 or 10 per cent of their weight of hydrochloric acid, and thus become available for use, the efficacy of the resulting preparations would be in any way impaired.

The small quantity of hydrochloric acid used in the process is sufficient to ensure the entire removal of the alkaloids from barks of average, and even more than average, quality. I have avoided the use of more than appears to be necessary, because its action with heat is said to be injurious. A slight excess of acid would be dissipated in the final concentration or desiccation to which the extract is subjected. I have ascertained that by following the instructions given the whole of the alkaloids extracted from the bark is within a small fraction contained in the dry extract in a soluble state. These alkaloids are associated in the extract and also in the liquid extract with other constituents of the bark which partake of the general character of some of the extractive matter of the *liquid extract of yellow cinchona* of our Pharmacopœia, but in one respect there is a marked difference between the two liquid extracts. There is nothing contained in the preparations made by this process that is not freely soluble in water, and therefore there is no precipitation or turbidity produced by aqueous dilution.

Having obtained several varieties of the red barks of commerce for the purpose of comparing the results obtained from them by this process, I have observed that they do not all yield the same sort of extract, arising from the fact that some are much richer in quinovin and red chinchonic than others. The thick flat varieties are the richest in those worthless constituents, while the thin young bark which, having been removed from the small branches with a spokeshave, is imported in small chips, is comparatively free from anything that causes turbidity on diluting the first concentrated extract with water.

This result, however, does not interfere with my process. The dilution would still be adopted as a safeguard, and being adopted the final results will then, as far as I have yet observed, be uniform or nearly so.

The formation of dry extract as a preliminary step towards the production of liquid extract was adopted for the purpose of facilitating the adjustment of the alkaloidal strength of the latter; but the properties of this dry extract which is soluble in water, forming a clear solution, will probably suggest its employment for other purposes, especially where the entire absence of spirit may be desired.

In the production of the liquid extract on the large scale, as well as otherwise, it is probable that manufacturers will often avoid the trouble of drying the extract, and stop the evaporation when the liquid contains the specified proportion of alkaloids, or carry it a little beyond the required point and then dilute it to what is required.

There are some experimental results connected with the subject which I have not yet had time to complete, but I have thought it desirable at once to submit the essential features of this process for medical and pharmaceutical criticism, reserving further details for a subsequent communication.

DISCUSSION.

The President, in inviting a discussion, suggested that it should be confined exclusively to the subject of liquid extract of cinchona. He would only say, in passing, that the Professor had very ingeniously dropped his old friend and taken to the new one. He should be glad if he had thrown his first love over with something like courage. Possibly there were some gentlemen present who might have something to say for the so-called liquid extract of cinchona which now existed in the Pharmacopœia. With all due respect to the Professor, he must say that he had weakened the force of his argument by the first two paragraphs of his paper, for, in one place he referred to the value of the existing preparation, and then he stated in so many words that practically it was not very valuable.

Mr. Giles requested that before the discussion commenced, Professor Redwood would state what he meant by quiuovin.

Professor Redwood said that he found that the term was very generally used to represent a bitter amorphous extractive matter which was capable of being taken out from cinchona barks, and which after concentration was precipitated by dilution.

Dr. Paul said that he had listened to the paper with very great surprise, on account of the remarkable discrepancy between the statements contained in it and the position which Professor Redwood took up with regard to the liquid extract of cinchona on a previous occasion. About a year ago he (Dr. Paul) brought before the meeting some data which led him to conclude that the liquid extract of cinchona was not altogether what it was commonly believed to be, or what he believed such a preparation ought to be in regard to the drug from which it was prepared. One objection which he raised against the liquid extract of the Pharmacopœia was its invariable deficiency in the amount of alkaloids which it ought to contain, and that therefore the recommendations which were given of it were misleading to medical men. On that occasion Professor Redwood defended the preparation and the method of preparing it, and he characterized the objection that it did not contain the medicinal constituents of the bark as a very weak objection. The present paper, however, appeared to be a perfect recantation of the position which Professor Redwood previously took up. He now said that there was a strong ground of objection to the official mode of preparing liquor cinchonæ. That was precisely what he (Dr. Paul) had said a year ago. Indeed, Professor Redwood's present statement appeared to be a confession which admitted all the charges which he (Dr. PAUL) made against the preparation and the process by which it was prepared. The Professor might, however, have been somewhat more candid in his confession than he had been. In consequence of the vigorous defence which Professor Redwood made on the last occasion, he (Dr. Paul) was discouraged from following out the matter and had remained passive ever since. His objections to the official process were not received with favour, and there did not seem any prospect of a proposed substitute being better received; therefore when Professor Redwood spoke of the difficulty which he had had to get his freinds to undertake the investigation of the subject, it must be remembered that the difficulty was somewhat of his own creating. In commenting upon the chief objection to the liquor cinchonæ, that it did not contain all the medicinal constituents of bark, Professor Redwood instanced the infusion of camomile and asked who in his senses would think of objecting to that infusion because it did not fully represent all that was active in the camomile flower. It was remarkable that, after such a brief lapse of time, he should now come forward and abandon his former position and recommend the present preparation, because it fully represented the medicinal efficacy of the bark. It could not be supposed that in this short space of time the Professor had taken leave of his senses, and yet he now came with a recommendation which only a year ago he characterized as senseless. Then as to the material from which the new preparation was to be made, they were told that it was red bark. But what red bark? Certainly not the red bark of South America, which, however valuable it might be for making tooth powder, had very little febrifuge value, and would not serve for making the liquid extract. He apprehended that the bark used was the Indian red bark, which a year ago he was told was so utterly outside the pale of official pharmaceutical recognition that he was making an unwarrantable assumption in presuming to bring forward experiments made with that bark to show that the process in the Pharmacopœia was useless. His experience of the red bark of India, notwithstanding the favour with which it was regarded by some persons, was that it was about the worst bark which could possibly be used. It contained much objectionable material, which resembled extract of kino more than anything else, and he should judge that it was about the most unsuitable of any for pharmaceutical purpose. There was plenty of cinchona bark of the true calisaya or officinalis type, which he regarded as preferable, and which possessed the advantage of having very little of the red offensive looking and nauseous material which was precipitated by water; such bark contained a large percentage of alkaloid in which quinine preponderated. They were told at the last discussion that the reason that he obtained unfavourable results was a material not ordered in the Pharmacopœia. He (Dr. Paul) took it that in the lapse of time Professor Redwood had recognized the validity of the objections which he (Dr. Paul) raised on the former occasion, and that he had now sought to devise a process by which those objections could be avoided. As to the process itself, it consisted in treating Indian *Succirubra* bark, he supposed, not with water, but with dilute acid. He could not accept the representation that this was an aqueous treatment, seeing hydrochloric acid was employed. He should like to see some data which would enable them to judge how far the preparation, made with hydrochloric acid, really did represent the bark in every respect. That he believed to be the chief point about the whole of the preparations of bark. A great deal had been said about the relative efficacy of different preparations and medical opinions with regard to the water preparations had been alluded to. No doubt those opinions were deserving of respect, although they were not altogether intelligible in the present state of our knowledge. It appeared that the very strong predilection amongst medical men in favour of the decoction was due, not to the constituents which it contained, but to the manner in which the constituents were presented to the stomach. In all kinds of cinchona bark, he believed, the principal part of the alkaloids was in combination with cinchotannic acid, and in that form of combination the alkaloids were very sparingly soluble in water. The consequence was that the infusion which was made with cold water was the weakest of any; the decoction was stronger, but though the solubility of the cinchotannates was greater in hot water than in cold, a large quantity of cinchotannate was deposited when the water cooled. What remained was in the same state of combination as in the bark itself, and that, he believed, was one of the reasons why the decoction was preferred to any other preparation. With regard to the liquid extract, he thought that the same condition ought to be maintained, and that an attempt should be made to avoid the elimination of the cinchotannic acid, and its decomposition, which took place very readily when it was liberated, so as to obtain a solution of the alkaloids in the state in which they existed in the bark. Professor Redwood had spoken of certain "worthless" constituents being eliminated. He (Dr. Paul) failed to see on what authority Professor Redwood condemned those constituents, or why he assumed that the alkaloids contained in his finished preparation were in the state in which it was desirable they should exist. This must be left for further inquiry. His (Dr. Paul's) own opinion was that the use of hydrochloric acid in preparing liquid extract was decidedly objectionable. Professor Redwood had stated that there was nothing in the preparation made by the process which he had now described which was not freely soluble in water. Consequently there was no cinchotannate of the alkaloid, and it might be inferred that this had been decomposed. This was in fact shown by the absence of turbidity on diluting the new preparation with water. The cinchotannate was, however, precisely the constituent which it was desirable to retain in a liquid extract. As to the exhaustion of the bark, there were no data showing that the new process was efficient. He was inclined to doubt whether treatment with weak acid would extract the whole of the alkaloids. The objections which he urged to the process were chiefly

made on chemical grounds. He would leave the pharmaceutical part of the discussion to others who were more competent to deal with it.

Mr. Giles said that he thought that it was perfectly immaterial whether Professor Redwood had changed his opinion or not, but he should like to say a word for the much abused old liquid extract. Some time ago having occasion to examine liquid extract of cinchona he obtained specimens of all the preparations known to the market, and amongst them, two samples of the Pharmacopœia liquid extract, one from a highly respected retail house, and the other from a manufacturing firm. The former contained 1·498 per cent and the latter 1·860 per cent of basic alkaloid. Pharmacopœia Calisaya bark ought to contain 2 per cent of basic alkaloid; and if those extracts which he examined were made from Pharmacopœia Calisaya they showed a very good result, for they contained nearly all the alkaloids that ought to have been present in the bark. He also examined some extracts which were very much advertised as being superior preparations. One of these contained 1·495 per cent of the alkaloids, and this was by far the highest percentage among those much advertised preparations. Battley's preparation gave a higher percentage, but for certain reasons he did not include it in the category. Hence, having regard to the lights which existed fourteen years ago, when the Pharmacopœia was compiled, the old Pharmacopœia preparation was not so disreputable. His experience was that medical men had very great faith in the old liquid extract when it was properly prepared. He believed that the reason was that the bark contained constituents of very great value, which were not alkaloids. What was wanted was a preparation of bark. If simply the active principles were required the alkaloids themselves could be used. He was very suspicious when he heard his friend, Professor Redwood, proposing to turn out what he called "quinovin." It was a dangerous thing to begin turning out anything, and he did not see the necessity for it. With regard to the mode of preparation, he was very suspicious about the direction to macerate at a temperature of 180° F. His experience was that no good was to be got from a high temperature. Another part of the process given in the paper consisted in adding distilled water to the concentrated percolate and stirring together while a precipitate was forming. But he did not see why there should be any precipitate formed at all. He had evaporated large quantities down to a solid extract, which he found prefectly soluble. It was true that he did not use a temperature of 180° and that the evaporation was performed *in vacuo*. He questioned whether the process of precipitating by soda in the manner directed for estimating the percentage of alkaloid in the solid extract would be found to be reliable. He thought the precipitate so obtained would be likely to consist largely of cinchotannate and would give too high a result; but that was a detail which might be amended. His impression was that they knew very little about bark, and that it was a rash thing to say what part of it had a medicinal value and what part of it had not. He held that all the surroundings of the alkaloids were important, and that the real object in making an extract was to get out all that was soluble and could be retained in the solube condition. It was an easy thing for the Professor to cut the Gordian knot, by precipitating some of the material and filtering it out if he could not keep it in solution, and thus to obtain a soluble residuum. A soluble preparation might always be obtained in that way, but he did not think that that was a fair way of overcoming the difficulty. The Professor said, "The small quantity of hydrochloric acid used in the process is sufficient to ensure the entire removal of the alkaloids from barks of average and even more than average quality." He doubted that statement entirely. He did not know whether Professor Redwood had examined the marcs afterwards; but he (Mr. Giles) had often found 1 per cent of alkaloids left in a bark containing originally 7 or 8 per cent, although hydrochloric acid was used and the percolation was conducted precisely as directed in the present paper.

Professor Redwood said that he was prepared to show that there were no alkaloids left in the liquid.

Mr. Giles said that the recognition of the use of hydrochloric acid was an important advance in the process. Unless an acid was used there would be a waste of alkaloid. With all due respect to Dr. Paul, he believed that the hydrochloric acid dissolved the cinchotannates of the alkaloids as cinchotannates. He knew that, having dissolved them out, they could be got back again as cinchotannates, though that did not show that they had not undergone a change in the meantime.

Mr. Holmes said that he had tasted the extract on the table, and he found that the astringency had not been destroyed by the hydrochloric acid. He believed that hydrochloric acid was always present in the gastric juice, and therefore if the preparation was not submitted to the action of hydrochloric acid before it entered the stomach, it certainly was afterwards.

Mr. Dunstan said that he should think it extremely probable that the hydrochloric acid decomposed the cinchotannates, forming cinchotannic acid and chlorides of the alkaloids. He supposed that when Mr. Giles said that he could get back the cinchotannates, he meant by the addition of ammonia.

Mr. Giles said that he got them back by treating with acetate of soda.

Mr. Dunstan, resuming, said that that amounted to the same thing. Assuming that they could not get the cinchotannates out by water alone, the next best thing was to get out the cinchotannic acid and the alkaloid separately. That seemed to be what Professor Redwood did. He was struck with one point in connection with what Professor Redwood supposed to be the necessity of making a solid extract of cinchona. It seemed to him that a standard liquid extract could more easily be got by estimating the alkaloid in the strong solution, and then diluting it to the requisite extent. He supposed that it was a troublesome operation to evaporate the solution to dryness. On the other hand, if it was thought desirable to have a soluble solid extract in medicine it seemed unnecessary, if this were standardized, to have a separate liquid extract. During the reading of the paper he recollected very forcibly a remark made by Professor Huxley, which was that a scientific man should be strangled when he arrived at the age of fifty, for he then became an obstacle to progress. Professor Redwood, however, was a proof to the contrary, for he was now taking a decided step in the direction of progress in advocating a standard liquid extract which contained a specific amount of alkaloid.

Professor Bentley said that he imagined that the great advantage of using succirubra bark was, first, that it contained a good amount of alkaloids; secondly, that it was not very liable to vary; and thirdly, that a regular supply could be obtained. And in addition to these advantages it was a bark which could be readily recognized, and it could be generally procured free from any serious adulteration. Those were very important considerations in the selection of a bark for general use. Succirubra had high authority for its use, for Dr. Flückiger recommended it some years ago, although he said that in certain respects it was not equal to some other barks. It was the sole bark recognized in the German Pharmacopœia, and it had been introduced into the Pharmacopœia of the United States. It was also one of the barks mentioned in the new Paris Codex. Mr. Holmes had also ably advocated the use of the red bark, and therefore it did not come before the meeting as something which was unknown. He did not altogether agree with his colleague with regard to the turning out of certain substances. Bark contained many constituents, and it was not known how one substance might modify the action of another. He was speaking exclusively of Succirubra bark, which was obtained from plants cultivated in India and elsewhere.

Mr. Walter Hills, referring to the statement in the paper that the author had had some difficulty in persuading his pharmaceutical friends to publish their modes of preparation, said that, after that discussion, and after the change which had been made, they might hope that those who had worked at the subject would make known some of the results of their work.

Mr. Tanner said that he was very pleased to find Professor Redwood advocating a liquid extract representing a less amount of bark than the Pharmacopœia did. In the Pharmacopœia preparations, four ounces of bark were used, and that on all hands was shown to be an unnecessary concentration. With regard to Mr. Giles's remarks about the assay of certain samples of liquid extract, he wished to ask Mr. Giles whether he took into account the fact that the Pharmacopœia used four ounces.

Mr. Giles said that he had not done so. He had overlooked that circumstance when making the comparison, which should have been confined to the relative alkaloidal strength of the pharmacopœial and other liquid extracts.

Mr. Hadfield said that the method by which Professor Redwood had got at the percentages of the alkaloids contained in the liquid extract seemed to him to be rather crude. He thought that a better result would be obtained from the solid extract of which Professor Redwood had spoken, and that the alkaloids of the solid extract would be better represented by previously obtaining an analysis of the bark. Of course this method would involve more trouble.

Dr. Paul said that in a case of perfect exhaustion the quantity of quinine which ought to be contained in a fluid extract made from a two per cent bark—the minimum laid down in the Pharmacopœia—would be 35 grains in the fluid ounce. In the case of ten samples which he examined a year ago, however, the total alkaloids only ranged from 2 to 10 grains in the fluid ounce, and then the greater part was alkaloid other than quinine.

Professor Redwood, in reply, said that his object in taking up the subject before the meeting was to elicit from other people the best means of producing a preparation of bark which had been much extolled by medical men, and most severely criticised and condemned by pharmaceutical speakers in that room. He certainly felt that it would be more becoming on the part of those who had so strongly criticized the liquid extract of bark if they had indicated in what way a preparation having a similar object could be more satisfactorily produced. He had failed to induce anybody to take the matter up. He had been pleased to find that, in the present discussion, the criticisms had been rather criticisms of his conduct than criticisms of his paper. He had desired to ascertain the opinion of competent pharmacists as to the process which he had suggested, but he was told that he stood in a false position. He gathered that he had been looked upon as the author of the Pharmacopœia preparation, and he had been asked how he could come and condemn it. The origin of that preparation was well known, and he was not aware that it was at all inconsistent to hold by it until a better was known. That was precisely what he had endeavoured to do on the former occasion. He certainly at that time took exception to Dr. Paul's paper, because there were too many assumptions in it, and it criticized a preparation that was not the Pharmacopœia preparation at all. Years ago, when he occupied the position which was now held by Dr. Paul, nearly all the barks which came into the London market were regularly analysed by him and reported upon, and therefore he could not fail to be perfectly familiar with the chemistry of the cinchona barks. But all that he had contended for was that in the absence of any better preparation they were justified in holding to that of the Pharmacopœia. Mr. Giles had very fairly commented upon the process described in the paper, but he (Professor Redwood) did not think that Mr. Giles had in any respect damaged his position or shaken his conclusions. Mr. Giles had not shown a better way by which the valuable constituents of cinchona bark could be taken out; and he (Professor Redwood) gathered from Mr. Giles's statement that his method was the right one. Mr. Giles's strongest objection was that the process described excluded from the finished preparation something which he thought ought to be retained. Upon that point he (Professor Redwood) was at issue with him. He did not think it desirable to leave all the extractive matter in the finished preparation. What he did consider desirable was to have a preparation which would dilute with water and form a clear liquid, possessing the astringency and the aromatic flavour of good bark. He had obtained this, and he had turned out the red cinchonic and what he had termed quinovin, a body which Mr. Howard designated as a nauseous bitter which was highly objectionable in the administration of the bark. The liquid extract of the Pharmacopœia and other extracts which professed to resemble it, and even that which was ordered in the United States Pharmacopœia, all possessed the grave defect of throwing down a copious precipitate of a nauseous disagreeable bitter when they were diluted, and this was a substance which he conceived to interfere with the efficacy of the medicine. Mr. Dunstan had made a very proper suggestion with reference to the preparation of a dry extract as well as the liquid extract. He (Professor Redwood) had admitted in the paper that perhaps most producers of the liquid extract would not take the trouble of getting the dry extract first. It had been suggested to him that the dry extract would be found to be highly hygroscopic, and very difficult of preservation. He had endeavoured to satisfy himself on that point, and he had left some of the solid extract exposed in a dish in his room for a week. The test to which it had been subjected was an exceedingly severe one. He admitted that it attracted moisture and softened, but it is hygroscopic character was not greater than would be expected in a dry extract of that description. He looked upon this preparation as one which would one day admit of use in medicine. An infusion or decoction would be better made from such a dry extract than by the ordinary mode, but there was a little difficulty in making a standardized dry extract of definite strength. Experiments would have to be made on that point, but he had been anxious to bring forward his present preparation before the meetings of the session terminated, in order that it might be criticized and tested by good pharmacists. He had put himself in communication with such men as merchants who were dealing with these barks, and the opinion which they had uniformly expressed was that succirubra bark would be the bark of the future, as far as application in pharmacy was concerned. It was not the object of his paper to indicate what ought to be the characters of the succirubra bark which was selected for use. That was a perfectly distinct question, in which he should look to his colleague (Professor Bentley) to take a leading part. Mr. Howard had told him that there was an abundance of succirubra bark which contained more than 10 per cent of the mixed alkaloids. In his paper he had put out of account the low class barks; but, taking the Indian succirubra bark, he maintained that the process which he had given was a process which was applicable to any such bark, and that by means of it they could get a valuable and suitable preparation for use in medicine. He had not yet been able to get samples of all the various qualities of succirubra bark. He was desirous of taking a low class, a medium, and a high class, and ascertaining whether there was any fixed relationship between the alkaloidal strength and the amount of extractive matter, or what he might call the extractive strength, of the different qualities. He wished to ascertain whether the cinchotannic acid, and the fine aroma and flavour which he regarded as one of the most valuable medicinal constituents of the bark, bore any fixed relationship to the alkaloids which were present, in the same way that, according to Mr. Dunstan's showing, the extractive matter of nux vomica bore a uniform relationship to the alkaloids contained in the drug. This was one of the points which would have to be determined before an extract of this description could be standardized. Mr. Giles had thrown out a doubt whether the small quantity of hydrochloric acid which was used was sufficient to exhaust the bark. He could vouch for the fact that the liquid which came off at the end of the percolation gave not a trace of precipitate of any kind upon the addition of an excess of caustic soda, but remained perfectly clear. He therefore contended that the whole of the alkaloids were taken out. He might further state that after having exhausted the bark and evaporated the percolate down to a low extent he got a precipitate upon adding water. Mr. Giles had said that he need not get a precipitate. He should like Mr. Giles to explain how it could be avoided. Some barks gave a precipitate like thick mud, while other qualities gave very little; but, whatever bark was used, he held that dilution with water and the throwing down of such precipitate as might be formed were desirable, and that this method gave a result which was in every way superior to that which was obtained when the precipitate was left in the preparation.

The President said that the Professor had been wonderfully strong in reply, as he always was. It was almost a greater treat to hear him reply to than to hear him read a paper, for the reply contained a fire which the paper often lacked. He must confess that his reply was strong, except in one respect. When he told them, with the dignity of a Professor, that because he found no alkaloid in the percolate, the bark was exhausted, he must forgive him (the President) for saying that the statement was extremely weak. An analysis of the bark ought to be

made before they could accept the statement. Perhaps the Professor would modify his statement upon the point. He must congratulate the Professor upon the active way in which he was able to deal both with friends and with antagonists. He concluded by conveying the cordial thanks of the meeting to the Professor.—*Pharmaceutical Journal.*

BRITISH HONDURAS.

Mr. D. Morris, the Director of Public Gardens and Plantations in Jamaica, has given the result of his visit to the colony of British Honduras at the close of 1882, in the form of a small volume of 152 pages, under the title of *The Colony of British Honduras, its Resources and Prospects; with Particular Reference to its Indigenous Plants and Economic Productions.* Mr. Morris says in his preface that "In England little is known of British Honduras, and that little not of a very flattering character." Referring to the forests, the destruction of which is common in most tropical countries, Mr. Morris utters a word of warning against any extensive or reckless wood-cutting, but at the same time points out that it would be well for the Government to afford every reasonable help for the establishment of permanent plantations, and for attracting to the colony an intelligent race of planters possessing the necessary capital and energy. "At present," it is stated, "several hundred thousand acres of some of the finest lands to be found in any British dependency produce an annual export value (in Mahogany) of only £50,000. This sum is attained in Jamaica in the export value of such a 'minor product' as Oranges." It is pointed out as a new and somewhat startling fact that the export value of Oranges from Jamaica is equal to that of Mahogany, the great staple industry of British Honduras. It shows, however, the gradual change that is taking place in the development of the West India Islands by means of the American fruit trade. Mr. Morris looks forward to an extension of this fruit trade to British Honduras as one means of bringing prosperity to the colony, but he says at the same time he does not wish it to be inferred that the larger industries are not likely to succeed there; on the contrary, with available capital and a supply of labour no country could do better; thus extensive areas of land are suitable for the cultivation of the Sugar-cane, and further inland Cocoa plantations might cover hundreds of acres, and Coffee of the finest quality ought to flourish on the slopes and higher lands.

The chief industry of British Honduras is wood-cutting. Mahogany is exported to the extent of about 3,000,000 feet per annum, the cost of which, ready for shipment, is from £8 to £10 per 1,000 feet. The annual export of Logwood is about 15,000 tons, realising from £2 to £3 per ton. "Wood-cutting operations have now been carried on for more than 200 years, and as a result much of the finest timber has been cut down. There is, however, much fine timber still to be found in the interior, but probably beyond the reach of rivers; hence it is believed that the construction of a railway will not only advance other industries, but at the same time stimulate the production and export of the old staples of the colony."

The chief Pine of the colony is known as the Yellow Pine (Pinus cubensis). The timber of this is used only to a small extent for building purposes, owing, it is said, to the difficulty of sawing it. The wood is heavy, and would probably be very durable if properly seasoned; as it is, however, it is used chiefly for firewood and making torches, which are largely used in the Mahogany works. Mr. Morris says that an impression prevails in the colony that two species of Pine exist on the Pine ridges, distinguished as the white and yellow Pine, but that he was unable to distinguish between them. He suggests that if properly tapped they might yield good resin, and by distillation good turpentine.

Some interesting notes are given on the Cocoa that, cultivated in the South, is described as being probably forms of Theobroma Cacao, "but in other instances the characters approached more nearly to T. angustifolia, which is supposed to be a distinct species, and under cultivation in Guatemala. This last is no doubt the Tabasco Cacao of the Atlantic slopes of Central America, which is probably identical with the celebrated Socunusco Cacao of the Pacific slopes."

We cannot follow Mr. Morris through his numerous notes on other equally valuable plants. It will suffice to say that he pays considerable attention to indiarubber plants, the Sugar-cane, dyes, Rice, Maize, Cinchona, and other medicinal plants, tropical fruits and food-plants. At the end of the book a list of works and serials is given suitable for the use of tropical planters.—*Gardeners' Chronicle.*

TROPICAL PRODUCTS IN SOUTHERN INDIA.

(*From the Annual Report of the Agri-Horticultural Society of Madras.*)

The Season.—Again a most abnormal season has to be chronicled. From the Government Astronomer's "Abstract of the Mean Meteorological Condition of Madras compared with the average of past years" to be found in the Supplement of the Fort St. George *Gazette* of 15th January 1884, it appears that the total rainfall registered in 1883 at the Government Observatory, Madras, was 60·54 inches, being 11·83 inches above the average of 48·71 inches. From the same authority, too, we learn that the hottest day in 1883 was Her Imperial Majesty's Birthday, the 24th of May, when the thermometer in the shade reached 107·7; while on the coldest night, that of 28th December, it fell to 61·4. As might have been expected, a drought prolonged from November 1882 to June 1883, with an allowance of rain far below the average until October, followed by a downfall or series of downfalls as much above, involving much standing water, was hard upon vegetable life. Large numbers of the hardiest trees died in and around Madras, while the Society lost many of their new and most valued introductions. The *Landolphia florida*, Brazil nuts, and Sapucia nuts mentioned in last year's report all, or nearly all, gradually died out; while most of the Nutmegs, Mangosteens and *Amherstia nobilis*, which require a moist climate, followed the many of their kind tried before in the Society's Gardens. No large or valuable specimen trees however died in the Gardens. The copious rains of October, November and December, or some other natural influence, happily rescued the *Cycas* plants from the plague of grubs described last year, and each plant is now crowned with a grand whorl of perfect fronds.

Fibre Plants.—Of these *Fourcroya gigantea* may be placed in the front rank. The plant has long been known and grown in Madras under the name of "Mauritius Hemp," and yields here a fibre of great length, extending even to twelve feet. The demand for 100,000 plants of *Fourcroya* mentioned in last Annual Report, unfortunately fell through before it was possible to comply with it, the gentleman who required the plants having in addition to a considerable number obtained from the Society, collected as many as he could make use of from other places. Large numbers of young plants large and small, have, however, been distributed both in and near Madras and to distant parts of the Presidency, and no efforts have been spared to collect and store in the nurseries a large stock. The Society has at present a requisition on hand for 40,000 plants for the West Coast, where in a moister climate it will be interesting to hear whether its growth will be more luxuriant than in Madras.

Manilla Hemp.—The stock of *Musa textilis* possessed by the Society has been sufficient to meet the few demands for it made during the past year. The cost of cleaning and preparing this fibre has for the present apparently proved prohibitive; but it is hoped that the trials and experiments now in progress in connection with the recent exhibition in Calcutta, may result in bringing to light a machine suitable in prime cost and economy of working for the wants of the many who would willingly devote attention to this and similar large and easily grown fibre plants.

Rhea.—The failure of the many attempts to win the £5,000 premium offered by Government for the producer of a cheap and efficient machine for extracting the valuable fibre of *Bœhmeria nivea*, appears to have suppressed the interest formerly taken in this plant, and the large stock once possessed by the Society has unfortunately dwindled away to a few specimens. Recent experiments seem, however, to have awakened enterprise in this direction, and some demands for plants and enquiries on the subject have been lately received. The stock in the Gardens will be increased as rapidly as possible.

Bowstring Hemp.—The several species of *Sanseviera* of which the Society possesses four, passing in the Gardens

under the names *S. zeylanica*, *S. cylindrica*, *S. fasciata*, and *S. caniculata*, have also met with considerable attention. A large number of plants and cuttings have been distributed locally and to distant places, and some successful experiments have been made in propagation, which will enable the Society to comply with large demands on reasonable notice. Enquiries have also been received and answered as to the habits and capabilities of several other plants, as producers of fibres and paper making materials. The Manager of one of the Tambracherry Company's estates in the Wynaad, is reported to have sent to England a fibre gathered in the forest on one of his Company's estates, where it is said to grow in great profusion, which was valued in the London market at £70 per ton. The plant from which this fibre came is believed to be *Conocephalus niveus* Wight, (syns. *Morocarpus* or *Debregeasia longifolia*,) a common plant on the Neilgherry Hills, belonging to the natural order of Nettles (*Urticaceæ*), and well known to, and much used by the jungle men and coolies working on the coffee and other estates.

Calotropis gigantea is again provoking enquiry. It is one of our commonest wild shrubs and contains perhaps the best fibre in India, producing also in abundance a plastic gum well worthy of attention.

Paraguay Tea.—From the report on the Horticultural Gardens, Lucknow, published last year, we learn that efforts are being made there to grow *Ilex Paraguayensis* the source of "Mate," or "Paraguay Tea," now being advertised as a wholesome beverage in various English papers; that an healthy specimen is growing in the Wingfield Park at Lucknow; and that eight millions of pounds are said to be annually consumed in South America. This Society has for many years past possessed several handsome specimens of this plant, from which, though they have not been observed to flower in Madras, no difficulty is found in propagating freely. The habit of the plant here seems to be that of a large, spreading, and umbrageous shrub, with large, dark green, shining leaves, forming a most desirable tree to plant as a screen for unsightly objects, and one well worthy of being planted for its own beauty.

The Society will be glad to distribute plants to any one who will test and report on their economic value. That the plant as growing here has properties which will bear investigation, is proved by the experience of the Honorary Secretary, who having chewed a fresh gathered leaf found its effect on him to be that of a fairly violent emetic. A closely allied species *Ilex vomitoria* is said to be actually used by the natives in its own country for its emetic properties, a special pilgrimage being taken every spring to indulge in, or submit to its effects.*

The parent plant of those in the Society's Gardens was brought out from Kew by Mr. Henry, when he entered the Society's service as Superintendent in 1870, and specimens have since been sent to Bangalore, Poona and other places.

A large number of seedlings of *Theobroma cocoa* raised in the Gardens in 1882, were distributed to Planters on the Shevaroy and Neilgherry Hills, and three or four plants reserved for the Gardens have thriven amazingly, so much so, that it seems to be almost possible that the Members of this Society may one day consume chocolate grown and manufactured in Madras. A slightly older specimen planted out in the coconut tope in partial shade, actually flowered and set fruit. Many previous experiments with cocoa in Madras have failed. It does well at Burliar.

PALMYRA TODDY AND JAGGERY.

Much has been said and written of late about the reforestation of India. In an agricultural country like this, where the prosperity and well-being of the masses depend largely on the abundance and regularity of the periodical rains, I can hardly conceive of anything more important than to conserve the existing forests; to re-clothe the denuded hills and arid plains with vegetation, and thus to ensure a permanent and lasting water supply. *Apropos* of the subject, it occurs to me, however, that in carrying out this desirable object, very little notice has yet been taken of the palms and other indigenous *flora* whose value and utility are well understood by the masses; while exotics like coffee, tea, cinchona, and the like have received an almost exclusive attention. This is the more strange when the very highest authority on the subject, Mr. Brandis, Inspector-General of Forests with the Government of India, says:—"The great beauty of Coimbatore is due to the fine stretch of paddy cultivation and the palm forests. I have been told that these last yield from R50 to R100 per acre, but I think even R200 would not be an excessive estimate." I suppose Mr. Brandis refers to the coconut and not the palmyra, but it is an open question which of the two is of greater value and utility to man. Except that the former requires constant irrigation and the latter none, there is not much to choose between them; and consequently the following observations on the manifold uses of the palmyra tree apply with a few exceptions to the coconut also. I may observe, in the first place, that the palmyra fruit yields no less than five different products, of which four are edible, viz., the starchy bulb or the palmyra in *embryo* of four months' growth; the sweet whitish sponge-like substance into which the kernel is then found to have been transformed; the yellow fibrous pulp or outer covering of the ripe fruit divested of the rind; the cool delicious gelatine-like kernel of the young fruit; and, finally, the oil extracted from the ripe kernel. The timber is valuable as furnishing excellent material for rafters, joists, and the like, and what is more, improves by age in the living tree so much as to become quite dark, and hardly distinguishable at a distance from the finest ebony. Need I speak of the leaves which form the ordinary covering of a hut in these parts; of the thousand-and-one fantastic shapes they are made to assume, when wrought into baskets, jars, knife-cases, betel-holders, trays, &c., and of their important use as substitutes for paper from time immemorial.

But the most important, because the most valuable, product of all is the Sugar extracted from the juice or toddy, and which in commercial terminology goes by the name of *Jaggery*. There are only two varieties of the tree, the *male* and the *female*, and toddy is obtained from both by bruising the flower-stalk (or raceme), and otherwise manipulating it so as to induce the exudation of the wine. What is known as "sweet toddy" is wine whose fermentation (or "vinous process," as doctors call it) has been arrested by lime, thinly laid on or rubbed in beforehand with a massive brush on the internal surface of the pot or receptacle. It is this harmless unfermented wine that, when boiled down, produces the *Jaggery* of commerce. The pure unmedicated wine or toddy begins to ferment in the pot itself, and soon becomes a frothing spirituous liquor like beer, and highly intoxicating. Its production and sale is therefore regulated by government, who derive a pretty considerable revenue by leasing out the monopoly for stated periods to the highest bidder. Agreeably to the general rule in India of each caste clinging tenaciously to its own hereditary occupation, the profession of climbing, manipulating, and drawing toddy from the tree, perilous and difficult as it is, is still monopolised by a non-Aryan tribe of the name of *Shanars*. It has always been with me a curious sight, somewhat bordering on the ludicrous, to behold the climber go about in the recesses of the grove, strangely armed and accoutred, like some knight-errant of the middle ages hastening forth to the tournament or the battle-field. His peculiar *turban*, fashioned not unlike a helmet; the *crutch* or substitute for a ladder which he carries on his shoulder in the manner of a battle-axe; the leathern cuirass and belt; his nether garments tucked up to the waist; his wooden sandals and the knapsack or weapon-basket dangling behind containing his brush, pincers, bill-hooks, and a quantity of lime—all these conspire to give him a *quasi* martial appearance at least. Thrice during the twenty-four hours has the poor fellow to climb and pare the flower-stalk afresh to expedite the flow of the saccharine juice; but it is at 3 or 4 a.m. that the toddy is brought down to the booths or temporary structures containing the stove and other apparatus employed in converting it into Sugar. Throughout the toddy season, which lasts from February until August, may be seen in the impervious gloom of the early morning these primitive stoves blazing up like so many *ignes fatui*, endeavouring to dispel the surrounding darkness. The toddy is first filtered and then poured into as many earthen pots as the stove has

* *Vide* Tropical Agriculturist, Vol. 3, page 169.

mouths. The liquor is then kept boiling until reduced to the required consistency. If intended for molasses, the woman who attends to the boiling dips her ladle in the liquor, and then empties it into the pot by turning it upside down; and this she does at intervals until a portion of the syrup held in the ladle sticks to the brim and falls in two instalments after the rest. The pots are then dismounted from the stove, and their contents collected into one capacious jar, which is at once hermetically sealed up and laid by for future use—only to be opened months afterwards as occasion may arise. Crystallization sets in almost immediately, but the longer the pots are kept unopened the more successful is the process. For manufacturing *Jaggery*, the toddy is boiled for a longer time than for Molasses, that is, until the syrup becomes so thick that a little of it (just enough to be held between the thumb and the index of the right hand) can be shaped by the action of the two fingers into a tiny little ball. The pots are now removed from the fire, and their contents collected into one large receptacle, and beaten with a stick for half an hour or so, until the surface shows a disposition to dry. This thick semi-liquid mass is then poured into moulds, and left to harden, which it does in twenty minutes.

A few remarks as to the export trade in *Jaggery* may not be out of place. I should think that Tinnevelly produces the largest quantity of any province in the Madras Presidency, as it contains more palmyras than any other. In parts where the *Pariahs* and other out-castes predominate, you are sure to see a toddy-stall affording a cheap means of inebriation to the poor fellows, who often enough transport themselves to the seventh heaven, and stagger about, for the nonce, "monarchs of all they survey." Apart from this questionable use of the tree, nearly one-third of the "sweet toddy" is drunk not merely as a beverage but as a substitute for food by the poorer classes; and I shall not be far wrong if I estimate the quantity of *Jaggery* consumed or reserved for family use at one-third of the whole produce. The *Jaggery* season, properly so-called, is from February to August, and the supply attains its climax in April, and gradually diminishes until September or October, when little or nothing is to be had in the market. And with other things, so in the case of *Jaggery*, the price *goes up* as the supply *goes down*; so much so that you can buy twice as much in April as you can for the same money in September or October. The average local price of a *candy* of 500 lb. in April is R9, but the European exporter depends for the supply on so many intermediate agents, who naturally charge something each for their trouble, that the cost is well-nigh doubled as the article reaches his hands. Let me explain. In the heart of the palmyra region, *Jaggery* sells in April at R9 per 500 lb.; two *candies* are a bandy-load and cart hire for the same down to Tuticorin is R3; add one rupee and eight annas (being the cost of six gunny bags to pack the two *candies* in) at as. 4 per bag; allow commission at rupee one per *candy*; and the total cost comes to R24-8 for a bandy-load, or 1,000 lb. Now, instead of endeavouring to minimise the incidental expenses and so to obtain the *Jaggery* at as near a rate to the local price as possible, the European firms simply play into the hands of contractors or other agents by accepting the latter's statements as true. I am told, but know not how it is, that even at the present moment they are advancing sums for *Jaggery* at R18 per *candy* of 500 lb., to be delivered in April; that is to say, they are paying exactly one-third more than they ought, as will be evident from what I have stated above.—S. A. D.—*Cor. Indian Agriculturist.*

AGRICULTURE ON THE CONTINENT OF EUROPE.

(*Special Letter.*)

PARIS, May 17th.

The prejudice, now on the high road to extinction against precocious and symmetrical stock, has had chief reason that the flesh of young animals was neither so succulent nor so nutritive as aged animals. Whether that was ill or well founded, the opinion of the pounds, shillings and pence farmers was that it was more profitable to sell off a fat ox when two years old than when four, a sheep at fourteen months, and a pig at eight. It has been demonstrated that the quantity of meat produced by stock delivered to the butcher at the above precocious ages costs exactly one-half less expense. An ox sold off at two years, instead of at four, implies a double profit in point of meat realised for the market, the return of the capital invested in half less time; the allowing of the sheds to be occupied with double the number of stock, without any augmented demand on food.

It has been alleged that an ox aged four years yields a greater or a heavier quantity of flesh than an ox of two years. This requires explanation. It is now ascertained that an ox from its birth, till it is two years of age, yields as much flesh as an animal of four years, provided the young ox be fed carefully, plentifully and methodically; that is to say, there shall be no starvation or short common stoppages in the rations. Now it is a law of physiological growth, that the time lost by insufficient feeding or the absence of sanitary care in the development of animals can never be recovered. In the first two years of its growth, the assimilation of food and the formation of the tissues of an ox proceed the most actively. No food is thus lost on the system; all is applied to build up, nothing is demanded for repairs. At two years, then, the period of development terminates, and henceforward the animal has, not only to feed to keep up life, but to repair the daily waste of the tissues. Thus more food is necessary to produce a pound of flesh, when after two years the tissues have to be restored than before and up to that period, when all vitality is not repairing wastes but developing growth.

Equally erroneous is the impression that an animal must be developed fully before it can be fattened. This is quite true in the case of unameliorated races so difficult to develop, so hard to feed, so bony and so skinny. But the wide-awake farmer does not seek such animals for fattening ends; he tries to obtain a precocious race, whether in cattle, sheep or pigs—animals well-formed, of agreeable conformation, pleasing to the eye, and so more certain to prove satisfactory for the purse. As to the alleged inferiority in quality of young, over-aged meat, ask any judge at a Cattle Show; note their awards; inquire of any butcher if a well-bred, well-fed ox at two years has not a more agreeable flesh, or, if you like, as good as the ordinary animal aged four; if a sheep, similarly cared, aged one year, does not produce meat as highly-relished as the animal double its age. In thus patronizing younger stock, capital is doubled and profits increased 100 per cent without any augmentation under the heads of food or labour.

Messrs. Gayot & Bouley are admitted authorities on all that relates to horse-breeding. The former has re-championed the plan of giving foals about one dessert spoonful per day of bone-powder mixed in the oats or bran. He testifies to have received from three departments in France the most satisfactory accounts of the efficacy of this adjunct to the rapid and strong development of the bony system in young horses. The effect has been very marked in the case of farmers rearing colts on granitic or schistose soils. Other breeders give the phosphate in its precipitate or chemical form: a good quarter of an ounce daily for animals between one and two years of age, one-half more for two to three years, and double the quantity for horses three to four years. The objections of M. Bouley consist in that he has ever found the phosphate so administered pass off with the excrements of the animal, and never absorbed into the system, and that more exactitude is required to control the experiments.

Professor Pyro advocates the permanent supply of water in cattle-sheds, so that the animals can drink at will. Ordinarily, stock is watered twice a day; the animal takes too much at a time, and perhaps at the improper moment. If left free with its trough, the animal may often patronize it a dozen times during the twenty-four hours, and in convenient draughts. In any case his suggestions relative to having the water kept in a reservoir in the shed, so that it can possess the temperature of the animal's body, and not some 7 or 8 degrees of a lower temperature, is worth reflection.

The breeders of the celebrated Percheron horses intend henceforth to hold an annual Show for their important speciality. The first Show will be held at Nogent-le-Rotrou, department of Eure-et-Loir, on the 22nd inst., and will last three days. Double the number of entries (500) were registered than there were boxes to accommodate; so only one-half the number of horses will be admitted

The breeders of Percherons are bestowing all their attention on keeping the sires of pure blood; for the more the sire is pure, the more the progeny will be pure. This is not ever true, as the Arabs count as much on pure-blooded mares as on stations. Further, take a pure greyhound bitch, cross her with a common dog, the pups will resemble more herself than the dog.

Much attention is fixed on the new Agricultural Academy opened at Kerliver, near Davulus, departément of Finistère, for girls. M. de Montigny left his castle and his fortune to train up girls to be all that a good farmer's wife ought to be, or a female farm-servant expected to be. The State and Department will endow the institution with 12,000 fr. a year. It opens under the direction of Mdle. Couturier, who was employed during five years as housekeeper at the Grignon College.

The Government has opened a most valuable office in Paris, and the idea will be extended to other cities, that, for testing the qualities of all seeds as to purity, soundness, vegetative power and freedom from weed-seeds. For a fee ranging from 1 to 3 fr., a farmer can have thus a legal test and guarantee for his seeds.

Many farmers who suffer from the white-worm or grub consider the best moment to destroy that pest is when it takes to the surface layer of humid soil; it cannot exist without humidity, and it penetrates accordingly into the soil to discover this. Weedings and hoeings are the remedies; the worm, before going deeper into the soil, tries to maintain itself to the roots of the plant. It has been observed that every three years the white-worm creates more ravages than ordinarily; this triennial period can be easily known, and all rubbish about headlands and ditches should be removed, such being so many breeding beds for the larvæ.

Attention is being drawn to the fact, that, in the vexed question of the best varieties of sugar-beet, more study has been paid to the manures than to the actual nature and preparation of the soil. It is now commencing to be seen that land deeply pulverized prevents the roots from forking, encourages a greater development of saccharine tissue, and a heavier yield of roots without reducing the desired sugar properties. Italy is progressing in beet culture. A calculation made establishes the following:—That during the process of fattening, a sheep consumes a daily ration equal to 3½ per cent of its weight; an ox, 4 to 5 per cent. Further, an ox weighing 8 cwt. yields 5½ tons of manure, equal to half the quantity of three horses or 15 sheep. In France one horse is roughly estimated to equal five laborers, one ox to three laborers, and the work of a woman about the two-thirds of that of a man.

The controversy between the millers may be considered as settled on the relative advantages of bun stones or steel cylinders; the latter, known as the Hungarian plan, is now general.

Bee-farming is taking more and more extension, as the demand for the "sugar of the poor" augments. A hive generally yields about 10 fr. of honey a year. There is a disposition to distil it for hydromel, a very healthy drink and formerly in much request. Other novelty, that of cultivating elder fences, to convert the berries after fermentation into alcohol. A hundred yards of a good fence would yield fruit sufficient to give 30 quarts of spirit. The berries are also employed for jams.

The phlloxera has invaded six new departments in the year 1883. On the other hand many vineyards destroyed have been replanted with success, and lands hitherto untried laid down as vineyards. Soapsuds and petroleum is the latest "miraculous cure" announced. It is cheap, may that not affect its virtue.

The farmers of Algeria intend trying tea culture. It is said that cuttings of the Indian varieties suit best. Formerly the culture of tea was attempted in the South of France and in Corsica under Louis XVI., but the inhabitants did not devote any special care to the culture. The requirements for tea are about the same as for the orange and the camelia. Climate is fickle and must be reckoned with. Thus pepper and clove shrubs were introduced to Cayenne from Singapore and succeeded, but the nutmeg and cinnamon culture proved a failure.

The vexed question of the impost on beet-sugar industry is about to be settled by levying the duty henceforth on the roots as in Germany. It is said the German sugar is richer than that produced in France, but it must not be forgotten that it is France which supplies Germany with large quantities of beet seed.

The prospects of French farmers are not bright this year; the frost has played terrible havoc with vines and cereals. Then the revenue is on the decline; this means no reduction of promised taxation.

PRUNING a fruit tree while dormant will tend more to promote a growth of wood than the production of fruit. Pruning after the tree has come in full foliage promotes fruitfulness, by giving a check to the growth, just as root pruning does.—*Farmers' Review.*

PLANTS IN COMBINATION.—The recent reference in our columns to the practice of growing plants in combination, when such plants are susceptible of lending beauty or affording support to one another, has elicited from a correspondent, "S. C. H.," at Barraboo, New South Wales, mention of a striking combination seen by him four or five years ago on the Milton-road, Brisbane, Queensland. "A fine large symmetrical acacia nearly covered with the common passion flower, and a crimson Bougainvillea, all three in full bloom, formed, from the contrast of foliage, flower, and colour, a picture never to be forgotten."—*Australasian.*

COARSE BONE MEAL FOR POULTRY.—As our fowls are necessarily confined in small yards, we are obliged to supply them with all the essential kinds of food that they would eat if running at large. But previous to the past six months a full supply of shell-forming foods has always been at times neglected and "soft shelled" eggs or eggs without any shells, have followed from the neglect. About six months ago we began to feed our fowls on bones broken up to the average size of wheat kernels, and we have never seen a soft shelled egg since. The fowls are excessively fond of this food in small quantities, and a very small quantity suffices to satisfy them and to insure sufficient egg shell material. This quantity we have found to be a full handful given three times a week for every six hens.—*New Yorker.*

TOO MUCH IRRIGATION.—The old superstition that grapes and oranges need a great amount of irrigation has almost entirely lost its force. Towards the latter days of his experience as a horticulturist, the late Col. B. D. Wilson was of the opinion that an orange tree only needed 80 gallons of water a year, properly applied. As Col. Wilson was one of the most successful orange growers we have ever had, and as his fruit was of the best, there is something in his idea. As to grapes, which are often drowned out by irrigation, we are informed by Mr. Schoolgens, the superintendent of the extensive vineyards of the Messrs. Kohler and Frohling, in this city, that although he only irrigated this property once last season, and that in the winter, the yield of the Mission grape was 8½ tons for acre this year. Wise men will draw their own conclusions from these facts.—*Los Angeles Herald.*

WATERMELONS.—There are times when watermelons are a drug in the market, and the price offered for them does not pay for carriage. In America they are often turned to good account by converting them into syrup, and the product is said to be superior to sorghum molasses, and not far behind maple syrup. Dr. Bellamy, of Atlanta, Georgia, writes on this subject as follows:—"By a little and inexpensive manipulation water-melons can be converted into a rich delicious syrup, far surpassing in its fine fruity flavour that made from sorghum, or even the West India sugar-cane. If some enterprising chemist will discover a method of crystallising it, it will make a sugar doubtless equal to any in the market. To make this fine syrup requires no special apparatus; an old-fashioned cider press with a long lever—such as our grandfathers used to use—to squeeze or press the juice, and a pot or kettle large enough to boil the juice. The ordinary sorghum evaporators, so common all over the country, would answer the purpose admirably, or even a large dinner pot would answer on a small scale. When the juice is pressed out and boiled briskly for several hours the rosy-red colouring matter coagulates, rises to the surface, and is skimmed off in the form of foam, leaving the juice as clear as distilled water, and of a pale amber colour. Boiled a little longer it soon thickens in a rich, thick, fruity flavoured syrup, perfectly clear, and the colour of quince or apple jelly."—*Queenslander.*

UNDERGROUND IRRIGATION

is thus described by Col. Fisher, R.E., in the proceedings of the Madras Agri-Horticultural Society:—

"I have lately been trying a system of underground irrigation here which has given me the best results, and as it may not be commonly known, I send you an account of it as it may be of use to your Society, particularly for flower cultivation in India.

"I take a common tile whole and fix it in a bed of flowers about 3 or 4 inches deep, by loosening the earth, not removing it, and pour the water into this, which runs underground to the roots and does not rise on the surface of the ground at all, if the tile has been properly fixed; if the soil is very loose or porous, a little clay puddling is required round the tile, which is put into the ground by its smaller end. One or more tiles are required according to the size of bed, but I find one tile quite enough for an area of one yard diameter.

"For flowers in pots or boxes I use a small tin tube or pipe about 6 inches long and ½ inch in diameter, which is inserted in the pot and its top kept always on a level with the rim of the pot.

"By means of this system of irrigation it is quite practical to destroy all insects, &c., which are so destructive to plants in India. I find a solution of Phenyle, 1 in 50 parts of water, poured into these tiles or pipes, frees the plants of all insects, vermin, &c., as they leave the ground which is saturated below by it, and in the same manner it is quite possible to convey manure dissolved in water direct to the roots of plants, which I find nourishes them far more effectually than by the ordinary method of watering. The ground is also kept much cleaner and free from all caking, &c. It is of course necessary to water the plants occasionally in the ordinary way to clean the leaves, but there is a great saving in using the water, as I have detailed above both in Garden and flower cultivation.

"I am not aware that this system has ever been tried before in India, but I have found it so remarkably successful here, I have sent you the details in the hope it may be of some service to your Society, in furthering its objects and interests. I have at this time of the year many English flowers in full bloom by means of this method of irrigating."

Read the Honorary Secretary's letter, dated 4th March 1884, in reply.

Read also the following extracts from a further letter, from Colonel Fischer, R. E., dated 7th March, 1884:—

"So far as my experience goes with this system of underground irrigation, nothing can be more satisfactory; a bed of Larkspur which had never flowered for 12 months is now in full bloom: the German stock is also now in full flower, Balsam and Zinnias are all coming on well, so are Candytuft, Chrysanthemum, Amaranths, Poppies, Cornflowers, Larkspur, Mignonette, Centaurea, Asters, &c.

"I have Hollyhocks now nearly 8 feet high in full flower with 15 to 20 spikes per plant. I have 110 cauliflowers in excellent condition, and no appearance of running to stalk or leaf: each plant is in a single pot tile, sunk 3 inches into the ground and the whole bed does not occupy one-fifth the space that 150 plants do planted out in the usual way. As regards the cultivation by this system, I am of opinion the pipes should go down at least 3 feet between two rows of trees, otherwise the roots will come out at surface, but I have no means of trying this system on any scale and only suggest it for the consideration of your Committee. I beg to add I made no claim as an inventor, but submitted such results as I had obtained for use if approved of."

Resolved, that Colonel Fischer, R.E., be thanked for his interesting communication.

[Of course when tiles are mentioned, draining tiles, or rather earthenware pipes are meant. But for the expense, coffee grubs could be effectually disposed by sending down phenyle as described.—ED.]

NOTE ON KAMALA.*

BY WILLIAM KIRKBY, PH.C.

Kamala was not known in Europe as a drug until a very recent period. Before the year 1852 the only account of it is in the writings of Anslie, Roxburgh, Royle, and Buchanan. In that year, however, Port-Surgeon Vaughan met with it in the bazaar of Aden under the Arabic name of *wars*. Specimens obtained by him were forwarded to Mr. Daniel Hanbury, together with information concerning the same. The following information collected by him is found in his 'Notes on Drugs observed at Aden, Arabia':†—"*Wurrus* or *warus* is a red powder used chiefly as a dye. It is the produce of a plant resembling sesame. The plant rises to about 5 feet in height, bearing several separate bunches or clusters of small round seeds, which are covered with a description of flour; this, removed by gentle rubbing, constitutes the dye. Two kinds come into the market. The best comes from the interior, principally from the towns of O Badan and Gebla, and the districts of Yaffaee and Sjibul Rudfan. The second kind, brought by the Somalis of the opposite coast, comes from Harrer. The second quality is not so much valued, and does not realize the price of the kind which comes from the interior. A considerable quantity of the dye is exported to Bombay, being used at Surat by ladies for dyeing silk a light brown-yellow. The Arabs use it as a dye and as a medicine, internally, for leprosy, and externally, in solution, for freckles and pustules. Much of it finds its way to the Persian Gulf, being known as *asberg*." Dr. Vaughan goes on to say that the best quality sells for 24 rupees the maund, while the African variety sells for only 17 or 18 rupees the maund.

Mr. Hanbury‡ states that he showed the specimens he had received to Mr. Alexander Gibson, of Bombay, who was at that time in London. Mr. Gibson suggested to him that it was obtained from *Rottlera tinctoria*. He then proceeded to compare the drug with specimens in the museum of the Linnæan Society, and found that Mr. Gibson was correct in his surmise.

Kamala, as found in commerce, is a fine, mobile powder, of a dull red colour. Under the microscope it is seen to consist chiefly of translucent, bright red granules mixed with colourless stellate hairs. These hairs give the drug its dull appearance. The glands are spherical, rather irregularly so. Their diameter is from 70 to 120 mkm. (micromillimetres). They are flattened on one side, and are composed of a number of clavate cells enclosed in a pale yellow membrane. The cells are arranged in a radiate manner round a short stalk cell, which is not always visible, occupying the basal side of the gland. From ten to thirty of these cells may be seen on one side; the whole cell, however, contains from twenty to sixty of them. The cells are filled with a red resin, which is soluble in solution of caustic potash, alcohol, and ether. On treatment with solution of caustic potash the structure of the gland becomes plainly visible. On appropriate treatment, first with alcohol and afterwards with Schultz's solution or sulphuric acid and iodine, the cells are seen to be composed of cellulose, while the enclosing membrane is seen not to be cellulose.

Professor Flückiger§ says that he examined authentic specimens from the Calcutta Gardens. These were taken from *Mallotus Philippinensis* (*Rottlera tinctoria*), and he found them to agree entirely with the kamala of commerce.

From this it is plainly evident that the source of commercial kamala has been definitely settled.

Some years ago Messrs. Allen & Hanbury imported a remarkable kind of this drug from Aden. A full account will be found in 'Pharmacographia.' Mr. Hanbury forwarded a sample of this to Professor Flückiger, who submitted it to an exhaustive examination.¶ It differs from the ordinary variety in bulk, in having a *dark* red or violet colour. Microscopically examined it is at once seen to have quite a distinct structure. Solution of caustic potash dissolves the resin contained by the glands, and the general structure is easily seen. The glands are cylindrical, somewhat conical, and are composed, like the other, of resin cells enclosed by a membrane. The glands are from 170 to 200 mkm. long and from 70 to 100 mkm. broad. The hairs mixed with them are simple and long, when compared with the short stellate hairs of the common kind. Professor Flückiger is quite sure the two kinds are not obtained from the same plant.

Dr. Dymock, in his 'Vegetable Materia Medica of Western India, says:—"'*Wurs*,' or '*wurrus*,' which differs from genuine kamala in being a dark purple colour, is the gland of the leaf of a leguminous plant, *Flemingia congesta*,'

* Read before the Manchester Pharmaceutical Association.

† *Pharm. Journ.*, [1], xii., 385.
‡ *Pharm. Journ.*, [1], xii., 589.
§ *Pharm. Journ.*, [2], ix., 279.
¶ *Pharm. Journ.*, [2], vol. ix., 278.

He was not able to ascertain if it is collected in India or whether it is imported from Arabia. I have not had the pleasure of seeing Dr. Dymock's book; but it was the note, as above, which appeared in "The Month" of a recent number of the *Pharmaceutical Journal*, which first attracted my attention to kamala and its sources. Thinking it would be interesting to know if commercial kamala was entirely the produce of *M. Phillipinensis*, I obtained samples of the drug from various parts of the country. I find that everyone of the specimens obtained from dealers is genuine kamala.

Mr. E. M. Holmes, of the Pharmaceutical Society, has been kind enough to let me have samples of the specimens in the Society's Museum. The results of my examination are as follows:—

Sample marked "490 b," catalogued "Glands, covering fruit of *rottlera tinctoria*," is genuine kamala.

Sample marked "490 c," catalogued "Wurrus, first quality," is identical with the purple variety examined by Professor Flückiger and is presumably the one referred by Dr. Dymock to *Flemingia congesta*.

Sample marked "490 d," catalogued "Wurrus, second quality."—This is totally different from either of the other two varieties spoken of. I have been unable to find any record of a third kind of this drug. I therefore venture to put before you a short description of this specimen. The glands are from 50 to 170 mkm. long, and from 50 to 100 mkm. broad. When seen with the microscope in a dry state they are translucent and but faintly coloured yellow. In form they vary very considerably; in fact, there appears to be no prevailing form. They impart but little colour to ether, alcohol, or solution of caustic potash. The cells are devoid of any such resin as is seen in the other two kinds. In solution of caustic potash they swell considerably, and their structure is rendered clearly visible. They consist of a mass of cells, composed of cellulose, enclosed by a non-cellulose membrane. The cells are not arranged in any particular manner. The hairs are similar to those found in the purple variety, being quite simple.

On drawing Mr. Holmes's attention to this unknown(?) variety, he informed me that he believed it was the *second* kind mentioned by Dr. Vaughan in his 'Notes,' and this sample was probably given by him to Mr. Hanbury, who presented it to the Museum.

I trust that some further information regarding the plants yielding the second and third varieties of "wurrus" will soon be forthcoming.

Looking at the last sort from an economic point of view, it would appear to be worthless as a dye, whatever it may be as a medicine.

In conclusion, I beg to tender my thanks to Mr. Holmes, and to Mr. Elborne who has assisted me in obtaining specimens of the drug.—*Pharmaceutical Journal.*

ACACIA ARABICA.

the "babool" of India, is very fully discussed in the proceedings of the Madras Agri-Horticultural Society, thus:—

Read memorandum from the Director of Revenue Settlement and Agriculture, dated 13th February 1884, No. 406, communicating a circular from the Revenue and Agricultural Department, dated Calcutta, 6th February 1884, and the following note by Mr. Liotard on *Acacia arabica*, dated Calcutta, 12th January 1884:—

"The following are some of the native names of this tree: *Babla* in Bengali; *Babul*, *Keekar*, in the North-West Provinces, Oudh, Punjab, and parts of Bombay; *Babhar* in Sindh; *Karuveylam*, *Nellatuma* in the Madras Presidency.

"The pod itself does not seem to have any special name: it carries the name of the tree with the designation *singri* or *phal*, which means legume or fruit, thus *Babla-phal* in Bengali, *Babul-singri* in Hindustani.

"As the native names indicate, the *Acacia arabica* is found almost everywhere in India. It is common and abundant in parts of Sindh, the Punjab, the North-West Provinces and Bengal.

"It is of rapid growth and requires no water, flourishing in dry arid plains, and especially in tough clayey soils where other trees are rarely met with. It bears fruit in three or four years from the date of its first appearance, and the fruit ripens in February to April in different parts of the country.

"The legumes are used to a small extent by natives in some parts of India in dyeing cotton and woollen cloths, and in tanning and dyeing leather. In dyeing they are used as a substitute for the more expensive dye-stuffs.

"The processes employed by the native dyers (who are the only dyers in India) are of a primitive nature needing little description. The legumes are used when dry as well as when green. In either case they are simply crushed or pounded and boiled in water, the decoction resulting being the dye which, when used alone, produces shades of drab. Sometimes the dye is deepened into brown by using alum as a mordant, and sometimes it is rendered black with salts of iron: by the use of other ingredients violet and other colours are produced.

"Figures are not available to show either the quantity of the legumes used annually by the natives, or the supply procurable in different parts of the country, or the prices at which the legumes can be procured. But the quantities are probably large, and the prices cheap. The most favourable season for collecting the legumes seems to be the spring.

"The dried legumes were last year experimented with in London, and the result was 60 per cent of tannin matter (seeds not reckoned, being useless): the action of this tannin produced a beautiful light-coloured leather. The value of the dried legumes (*minus* the seed) was reckoned at £40 per ton.

"Probably the best method for exporters would be to dry the pods at the places where they are gathered, then to extract the seed, and finally to press the pods before despatching them.

"The bark also of the tree is used by natives both in tanning and dyeing, and more commonly than the legumes. The tree is ready for barking when eight or ten years old. It is then cut down from the roots, and the bark is taken off immediately while the sap is green. It is then dried in the sun, care being taken not to expose the inner side of the bark.

"The dye is extracted by simply steeping or boiling the bark in water, after it has been chopped in small pieces. When mixed with the barks of the khair (*Areca catechu*) and palas (*Butea frondosa*) trees a brown dye is produced. When mixed with sulphate of iron dyes of shades of grey ranging to dark brown are obtained.

"Both of these dyes are suitable for dyeing cotton cloths and are used in most of the provinces in India. But the bark is more used in tanning than in dyeing. In Bengal it is extensively used as a tan everywhere, being the cheapest and most effective tanning agent known. In the North-West Provinces likewise it is the commonest tanning agent in use, and the Government Saddle and Harness Factory uses from 1,000 to 1,200 tons of the *babul* bark in a year.

"Some experiments were made with the bark in 1881 in England by Mr. W. N. Evans of the Tanner's Laboratory at Taunton, and the result was a percentage of 18·95 of tannin. 'One fact worthy of notice with this bark,' Mr. Evans wrote, 'is the beautiful creamy white colour it gives when precipitated with gelatine, this being at present the only bark or tannin material that gives that colour.' The bark was valued at from £12 to £14 per ton in England.

"The extreme bulkiness of the bark in its natural state is, however, an impediment to its export, and it therefore occurred to the writer some two years ago, that it would be well to have the bark dried and then ground and bagged or baled tightly before export. Since then a notice has appeared in the Supplement to the *Scientific American*, of 29th April 1882, which shows that Mr. C. Kimplen, of Chicago (America), has patented a hydrostatic press, of which the object is to put ground tan-barks into the least possible space by forming them into blocks. The machine appears to be an expensive one, but the suggestion to have the dried *babul* bark ground and compressed in India for export seems worthy of consideration."

Read also letter from the Director of Revenue Settlement and Agriculture, dated Madras 12th March, 1884, No. 610-A, forwarding a memorandum on *Acacia arabica* by Mr. J. S. Gamble, Conservator of Forests; asking information regarding the commercial prospects of a trade in pods and bark with England and other countries; and stating that he is making enquiries regarding the purchasers in London and mode of sale, and as to the proximate annual yield in this Presidency.

Read the following memorandum by Mr. Gamble, dated 26th February 1884, referred to above:—

"The Babul is not indigenous in the Madras Presidency unless possibly it may be considered to be wild on the black cotton lands of Bellary and Kurnool. Nor is it a 'Forest tree' properly speaking in this presidency for it does not occur wild in any of our chief forest tracts. But it comes up plentifully, self-sown, on old tank beds, on fallow lands, on black cotton soil, and on bunds and mounds and high lands among the rice fields of the Circars and Carnatic. Its real home is probably to be found in Sind and Guzerat and in the first mentioned province it is the chief tree of the Indus bank forests, where it affords large supplies of fuel for the river steamers and the railway. The wood and its uses are described at page 151 of the 'Manual of Indian Timber' to the information given in which I have nothing to add, except that the Madras Railway refuse to take it as fuel, although other lines have no such prejudice. I understand. The refusal is due to the impression, right or wrong, that the products of combustion injure the boilers of the engines.

"In the re-afforestation of barren lands in suitable soils Babul is an extremely useful tree. It thrives well on the black cotton soil which is more than can be said of most other trees, its usual companions being *Albizzia Lebbek*, *Balanites Ægyptiaca*, *Parkinsonia aculeata* (an introduction), the Tamarind, Margosa and Wood apple. Old tank beds in most Madras districts quickly cover themselves with it, and indeed wherever there is a patch of fallow alluvial land along the districts of the eastern coast and a few trees to give seed it springs up in abundance. Goats being largely fed on the pods they are the principal agents in the distribution of the seed, and the value of the pods as an article of food for stock must not be forgotten in considering the possible effect of a large demand for them for tanning purposes. But the recent report on the value of both the pods and the bark for tanning are most valuable, and we shall bear them in mind in making future cuttings of Babul trees in the plantations, and self-sown Babul jungles of Bellary, Anantapur, Cuddapah and Kistna Districts. It would be useful if Mr. Liotard would inform us who are the purchasers in London who are likely to give £40 per ton for cleaned Babul pods and £12 to £14 per ton for bark (more than 50 per cent increase on the ordinary price of oak bark) and what is the usual method of sale. Are the tans sold like timber, tea, &c., at public sales, or are they merely consigned direct to the tanning firms? It would also be useful to know what prospect there is of firms in the presidency towns buying such tans as may be collected by forest owners or managers.

"At such rates as the above it is surprising that the tans have not long ago become regular articles of trade, and that Babul planting has not been carried on similarly to and much more extensively than that of the Casuarina in such localities as Madras, where cost of carriage to the seaport is low.

"Grown for the pods only and their yearly crop I expect the trees ought to be at least 30 feet apart, or 15 at first to be thinned out to thirty feet, to ensure a proper amount of air and sunlight for the full development of the fruit. This would give about 48 trees per acre, the yield of which can be calculated if the average yield of a tree is known. Grown for the bark it would probably be found most profitable to treat it in coppice and cut it over every 8 to 10 years. It would therefore require to be planted close say 10" × 10" or still better propagated by broad-cast sowing. The yield would probably be much the same as that of Oak bark, but actual experience only can tell what amount is likely to be realized per acre. The wood could at the time of cutting be also easily sold at good rates in any locality, away from the large forests, where Babul is grown. It will therefore be seen that different methods of planting must be adopted to secure the fruits and the bark, the former being an annual, the latter a periodical, crop.

"I should say that if only merchants can be found in our seaport towns to buy the Babul bark and pods, not to speak of other valuable tanning materials like the Taugedu or Avaram bark (*Cassia auriculata*), the barks of *Cassia Fistula*, *Acacia Leucophlœa*, *Terminalia tomantosa*, *etc.*, and the myrabolams, there is not likely to be much question of difficulty of supply. Our forest plantations and self-sown scrub jungles alone could furnish a great deal of bark, while a very large supply of pods would be given by the numerous village trees even if one-half of the produce is conceded to the goats."

The tree grows very abundantly in the neighbourhood of Madras, and enquiries are being made about it. Should any information not to be found in the above notes, "Drury's useful Plants," and similar well-known books of reference, be obtained, it will be forwarded.

PRUNING YOUNG TREES.—Experience has proved that the triple crotch is the strongest form of tree growth. Had you left two or four buds, dividing the tree into two equal divisions, in their after growth their weight would have been always apart from each other, and in some year of heavy fruitage your tree would have split in twain, losing you the time as well as your reward for the care bestowed upon it; whereas, the three limbs interlock their strong fibres around each other and give a triple strength to this foundation of your future tree, which insures it against any such after catastrophe.—*Leader.*

EFFECT OF PETROLEUM ON FRUIT TREES.—My gardener, at my suggestion, applied petroleum neat to about four hundred out of six hundred young apple, pear, plum, and cherry trees, from top to bottom, about Christmas last year. The trees were two and three years old, purchased from a nursery, ten months before, and had therefore been only ten months planted, and when planted had very coarse roots. Two pear trees are certainly dead, which I attribute to the coarseness of the roots when planted. The remainder of the trees appear to be pictures of health; many of the apple and plum trees are full of bloom; that on the pear trees, principally consisting of Marie Louise and Louise Bonne of Jersey being especially abundant. Two gallons of neat oil were used in the work.—G. B. WALKER (Farnbro). [If the dressing had been applied a few months later, not improbably most of the young trees would have been killed.—ED.]—*Field.*

HOW TO FERTILISE FRUIT TREES.—J. B.—Here and there on all farms and in most fruit gardens will be seen an occasional tree or grape vine which seems to lack vigor—does not grow well, and yet seems to have no particular disease. The probabilities are that the tree is dying of starvation, and needs a liberal supply of food. When you give it this ration do not pile a load of manure around the trunk of the tree on the body of a grape vine. That is just the place where it will do the least good. Nearest the trunk of the tree the roots are all large. The fibrous roots (the feeders) are further off, near the ends of the roots. These only can take up the nutriment. It is aways safe to assume that the roots extend as far from the trunk in every direction as do the limbs of the tree, and to properly fertilise spread the manure all over that area. Then fork it in and you have done a good work and done it well. If some disease has begun its work on the tree, you put the tree in a healthy vigorous condition, the better enabling it to successfully contend againsts its enemies. We have seen numerous old pear and apple trees, bearing poor and guarled fruit, which the owners consider of no value, but which such treatment as we have outlined above would restore to their original usefulness.—*Leader.*

SALTING THE SOIL.—Common salt spread upon the ground has the effect of aiding in the solution of mineral matters used in stiffening the stems of plants. If there is already a sufficiency of such matters in solution in the soil, an application of salt will do no good. Salt is most efficacious in swampy ground and wherever there is an excess of organic matter. It is not supposed to act directly as food for grain producing plants. If it does anything towards increasing grain crops, it does so by way of stiffening the straw and keeping it from lodging. Wherever salt is needed it often pays many times its cost, but there is so much land on which it does no good that it would be imprudent to use it to any large extent without first determining, in a small way, whether it will be useful or not. As its usefulness depends wholly upon the condition of the soil, no specific value can be fixed for it in advance of using it, as there can for barnyard manures and the commercial fertilisers, nor can it be used as a substitute for any of the real fertilisers or for land plaster. It is most frequently used for sowing on wheat in the spring, which it sometimes greatly benefits and sometimes not at all. Its specific action is most marked upon the beet family.—Professor L. B. ARNOLD.—*Leader.*

TIMBER IN NEW ZEALAND.—It is stated in the *Colonies and India* that the export of timber, especially Kauri (Dammara australis), from the northern part of New Zealand is very large; numbers of vessels are constantly employed carrying Kauri to the southern parts of the colony and to Australia, where there is a good market for it. In addition to this several large mills in Auckland are fully employed cutting up the logs into sizes fit for building purposes. Between 400 and 500 hands are engaged in this work alone.—*Gardeners' Chronicle.*

MANGOES IN QUEENSLAND.—We have received from Mr. A. Williams, of the Green Hill nursery, some large and well-matured fruit of the following choice mangoes:—Batavia. Rose, Strawberry, Malda, and a seedling of his own raising. The Malda specimens are very large, weighing quite 1½lb. each, of excellent flavour, and very juicy. The Rose is a small sized fruit with pink cheeks, and is very sweet and luscious. The Strawberry is of good size, and is already well and favourably known amongst lovers of this tropical fruit. The seedling, which has not yet been named, has a rather rough looking exterior, and attains to a good size; but for quality it can hardly be surpassed. Mr. Williams's crop has been moderately heavy this year notwithstanding the drought, which shows that under ordinarily favourable circumstances the mango is a great success in Queensland. It thrives admirably in the whole of the coast country, and should be found in every tropical and semi-tropical orchard. All the varieties mentioned above are either free of fibre altogether, or have very little of it; and this is a very important consideration in the mango.—*Queenslander.*

MEAT FOR TREES.—The belief in the carnivorous requirements of trees has not quite become an exploded matter in some parts of the Continent, if it has fortunately been banished from amongst ourselves. Many of the older members of the craft could tell some singular doings as to root feeding that occurred in the earlier years of this century, which would fairly pair off with the following:—A gardener in Prussia possessed an old Apple tree of the there well known Red Stettiner kind, which, in spite of all his care and endeavours, refused to bear fruit, but yet made very strong wood. In this difficulty he tried the effects of ringing the bark, but with but little result—the tree bore a few fruits, of which some fell off during the summer; but this was not the effect of too great a flow of sap, the ringing having possibly prevented that. It occurred to him at last that the roots were not obtaining the necessary food, and just then a horse died; this was cut up into pieces and buried in the soil round the tree, about as distant from the bole as the branches reached. The results that followed this operation were astounding, for the hitherto unfruitful tree has borne splendid crops of fruits ever since—of course, thanks to the buried horse-beef in its larder.—*Gardeners' Chronicle.*

DAMP CLAY PREFERABLE TO CHARCOAL FOR THE TRANSPORT OF SEEDS.—We quote as follows from the proceedings of the Madras Agri-Horticultural Society:—Read the following extract from the *Gardeners' Chronicle* of 8th March 1884, page 314:—"The use of charcoal as a medium in which to pack seeds to be sent to this country from abroad, is very common indeed; in fact, a considerable number of scientific correspondents seem to pin their faith to charcoal, as a packing agent, to a remarkable extent. As far as our experience goes, its use is, however, decidedly objectionable, as, apart from its dirtiness, it absorbs the moisture from the seeds, and in many cases so thoroughly, that all germinating power is lost by the time the package arrives at its destination. All short-lived seeds seem to travel best in damp clay or moist earth. Packed firmly in damp clay, Siebold succeeded in introducing tea seeds from the Chinese tea countries to Java, and also the seeds of a large number of oaks, camellias, and other Japanese plants from their ative country to Holland. Seeds of tea, coffee, and a host of other plants, which utterly fail to retain their germinative faculty during a lengthened sea voyage when packed either without any packing medium, or forwarded in charcoal, grow readily when treated in the manner adopted by Siebold. We are glad to see Mr. Prestoe condemning the use of charcoal in his last Report on the Trinidal Botanic Garden." Resolved, that the above extract, being likely to be of use to some of the Society's foreign correspondents, be published with these Proceedings. The remarks above are quite in accordance with frequent exeprience in the Gardens.

YOUNG CHICKS that are subject to weakness in the legs should receive a small allowance of fine bone meal in the food. Weak legs come from forced growth, high feeding, and close confinement, but it is not necessarily dangerous.—*Southern Planter.*

FLORA OF THE PHILIPPINES AND ITS PROBABLE DERIVATION.—Under this title a communication was laid before the Linnean Society (May 1) by Mr R. A. Rolfe, of Kew. As recently computed, the whole phænogamic vegetation consists of 3,564 species, belonging to 1,002 genera. Of 165 Dicotyledonous orders 119 are represented, and of Monocotyledons 25 out of 35; the Gymnospermeæ are poor in numbers. The proportion of vascular Cryptogams to Phænogams is nearly one-eighth, chiefly Ferns. Fifty-two species of Ferns are not known elsewhere—a significant fact. The endemic phænogamic plants consist of 917 species, or a proportion of over one quarter endemic; the Dicotyledons showing over one-third to be endemic, and the Monocotyledons a little over one-tenth, chiefly Orchids. A striking feature is the large number of endemic species, and the relatively few endemic genera. The flora, in some respects, may be said to have a Malayan aspect, but is wanting in many typical genera, even such as flourish profusely in the neighbouring island of Borneo. There is an appreciable Australian element mingled with the above; yet, taking all data into consideration, Mr. Rolfe arrives at the conclusion that the Philippines are truly insular in the essentials of their natural history—this not so much through there being an early separation of the Asiatic continent which had a dip under the sea (submergence alone causing extinction of genera as Mr. A. Wallace has inferred), but from their being largely volcanic and geologically speaking of recent origin—presumably what is believed to have been the case in certain other oceanic islands—the vegetation therefore modifying itself accordingly.—*Gardeners' Chronicle.*

TROPICAL PRODUCTS IN QUEENSLAND.—On Carroll's Creek, about thirty miles northwest from Cooktown (says the *Herald*), in an undulating, well-watered country, with magnificent soil and but little timber, Mr. James Dick holds 640 acres, a portion of which he has paddocked for grazing, another lot is cleared and cultivated as a nursery and fruit plantation, and the remaining and greater portion is reserved for sugar-growing. No expense has been spared in preparing the ground and in introducing and planting an endless variety of tropical plants, fruit trees, cereals, &c. There are 3,000 coffee plants in the nursery averaging 18 in. high, the product of seeds planted fifteen months ago, all healthy, although greatly retarded by last year's drought, and there are 2,000, which were planted nine months ago, averaging 2 ft. in height all remarkably healthy and evidently invigorated by late rains. These are principally Liberian, but of the next best thriving species, the Arabian, there are 500 plants from 3 ft. to 3½ ft. high, fresh and healthy, but not making such rapid progress as the Liberian. The Java seeds did not thrive well and but few plants are preserved. There are a few each orange, citron, lemon, nectarine, &c., trees, averaging about 3½ ft., and so healthy that they will probably bear next year. There are two fine specimens of the cinnamon apparently well acclimatised, but all the spice plants are hopelessly dead. There is a jack-fruit tree two years old which has reached 10 ft. and looks as if it would bear shortly. There is a fine nutmeg tree 8 ft. high, and from the profuse growth of the wild species in the neighbourhood, this ought to be profitable planting could the plants or seeds be procured in Brisbane. An indiarubber tree is shooting its thin stalk up rapidly, and has reached 6 ft., having made 3 ft. in less than four months. Several species of vines have been tried, but even the survivors do not present a very hopeful appearance. Two acres of cane were planted, the Cherribon, the Meera, and the Black Java thriving best in the order named, some of the first being now 8 ft. to 9 ft. high, but there being no mill within accessible distance, the cane was used as feed for cattle and pigs during the last dry season. Maize thrives well on the meadows bordering the creek, and with cheap transit to a market, its cultivation would pay splendidly. There are about thirty other specimens of tropical and Oriental fruit trees, the names of which it would be tedious to mention, all of them apparently well rooted and thriving. By last mail four varieties of cinchona and three of cardamom seeds were received from Ceylon and will be planted next week.—*Queenslander.*

IRRIGATION IN CEYLON, ANCIENT AND MODERN.

By JAMES ROBERT MOSSE, Esq., M. Inst. C.E.

The object of this paper is to give a brief account of the restoration of some of the ancient tanks in Ceylon, and of the result of the irrigation works which have been repaired or constructed chiefly during years in which I held the post of Director of Public Works in that Colony.

ANCIENT HISTORY.

The tanks in Ceylon are of very ancient origin, and of much historical interest. The late Sir Emerson Tennent, for several years Colonial Secretary in Ceylon, thus alludes to these tanks: (*a*) "The number of these stupendous works, which were formed by the early sovereigns of Ceylon about B.C. 104, almost exceeds credibility. Kings are named in the native annals each of whom made from fifteen to thirty, together with canals and all the appurtenances of irrigation."

Originally these vast undertakings were completed "for the benefit of the country," and "out of compassion for living creatures," but so early as the first century of the Christian Era they were frequently formed to enrich the land of the Buddhist temples.

Sir Emerson Tennent adds: (*b*) "Excepting the exaggerated dimensions of Lake Mœris in Central Egypt and the mysterious basin of Al-aram, the bursting of whose embankment devastated the Arabian city of Mareb, no similar constructions formed by any race, whether ancient or modern, exceed in colossal magnitude the stupendous tanks of Ceylon."

From a return made to Government it appears that in 1867 there were in all 4,903 tanks in Ceylon, but many of these were village tanks of small area, breached and out of repair, and many being fed by rainfall only, were frequently unserviceable.

(*c*) It appears that about B.C. 504, Panduwasa constructed a tank in the neighbourhood of the capital, Anuradhapura, the ancient Anurogrammum of Ptolemy, and this tank, the present Bassawakulam, was restored in 1867.

(*d*) About B.C. 307 Devenipiatissa formed the Tissawewa Tank in the neighbourhood of the great Buddhist temple Kattregam in the Southern Province, and this tank, estimated at about 3,000 acres in area, with a bund or dam 1,400 yards in length, was restored and enlarged in 1876.

(*e*) The Padivil Tank, situated in the Northern Province, is about fifteen square miles in area, the dam is eleven miles long, 30ft. wide on top, some 200ft. at the bottom, in places 70ft. high, and faced throughout its whole extent by steps of large squared stone. It still remains in ruins.

(*f*) The constructor of this tank is unknown; by some it has been ascribed to Maha Sen, A.D. 66. At any rate an inscription at Mihintala shows that previous to A.D. 275 it was the property of that temple.

(*g*) Native history records that, about A.D. 275, Maha Sen diverted by a large dam the water of the "Karaganga" river, near Matale, and formed a canal leading to the Lake of Minery (about 20 miles in circumference), also that he constructed sixteen large tanks, among others that at Kanthalay near Trincomalee, restored in 1876. (*h*) This tank, containing an area of fully 6 square miles in the rainy season, and seldom less than one in the driest, is enclosed by hills of moderate elevation covered with forest; the artificial dam by which it is retained is about 1¼ miles in length, about 50ft. in height, with a base of from 150 to 200 ft., the inner side being faced with a massive stone revetment.

(*i*) The Kalawewa Tank, formed by Dhatu-Sena, about A.D. 460, is one of the largest tanks in Ceylon. (*j*) Its catchment area appears to be not less than 120 square miles the tank is said to be about 40 miles in circuit, and about 10 square miles in area; the dam, averaging from 50 to 60 feet high, and 20 feet broad on the top, is about 5¼ miles in length; it is still in good preservation except at the great breach, 1,000 feet wide, whence the Kala Oya river issues. In common with many others in India and Ceylon, this fine tank appears to have been destroyed by the insufficient length (only 200 feet) of waste weir or *spill*-water, a result by no means extraordinary considering the heavy rainfall in this colony.

(*k*) From the Kalawewa an old channel called the Yodi-ela, 40 feet wide and 53 miles in length, which formerly carried the water to the capital, Anuradhapura, filling in its course the large tanks of Tissawewa, Bassawakulam, and Bulankulam, still exists. For the last four years the restoration of this tank and channel has been under the consideration of Government, but as the estimated cost of the repairs amounted to R545,500, work to the value of R89,430 only had up to 1882 been executed.

About A.D. 795, King Dappula improved the extensive works connected with the Minery Lake, situated in the neighbourhood of Pollonarrua, the second capital of Ceylon; and in A.D. 1071, Wijeyabahu I. repaired many of these works, which had been destroyed during the Solean interregnum.

About (*l*) A.D. 1153, Prakrama Bahu I. cut the Jayaganga canal to conduct the waters of the Kalawewa tank to Anuradhapura; he is said to have *constructed* (*m*) "1,407 tanks, and to have *repaired* 1,395." He also cut many canals for the purpose of diverting rivers into tanks "of such vast dimensions that they were known as the Seas of Prakrama;" and he formed the (*n*) Kaalinde Canal to conduct the waters of the Minery Lake to the northward.

Of the works of Prakrama Bahu, the Ellehára Canal was the most extensive, and, in an engineering view, the most remarkable. Commencing at Ellehára with an enormous stone dam across the Ambanganga river, formerly called the Karaganga a huge embankment, ranging from 40 to 90 feet high, and for many miles averaging 80 feet, was continued without intermission to Kondrowawe, a distance of 24 miles. By damming up the rivers, this embankment formed a series of lagoons, which probably were the "Seas of Prakrama," and from Ellehára to Kondrowawe they appear to have

been navigable by boats. From Kondrowawe a canal, some five miles in length, more in cutting than in embankment, conveyed the water, first to Minery Lake, and then afterwards to Kanthalay tank, formerly called Gantalawe, the whole length of the canal being 57 miles.

The most interesting engineering feature, the old stone dam across the "Ambanganga," was thus built; its breadth at the top is 33 yards, its height above the level of the water at ordinary seasons is 40 feet; it is built throughout of huge blocks of hewn stone embedded in mortar, which still remains in the interstices; the stones in the interior of the work were carved with figures, and evidently had formed part of a building of an earlier date; great engineering skill is shown in preparing the rock to receive the foundations of this stone dam. Upon the outer side these consist of a trench cut into the solid rock to receive the first layer of masonry; at a distance of 25 feet inwards is a continuous row of holes 2 feet square and 3 feet apart, and sunk to a depth of about 3 feet; into these were fitted large stone pillars, the remains of some of which, broken short off, are still to be seen, one of them protruding above the surface of the rock to a height of abont 2 feet. (o)

The system by which these ancient works were constructed was that which from time immemorial had existed in Ceylon, "Rajacaria," (*p*) or forced labour. To what extent and under what safeguards this system was enforced in early times is not known, but wherever labour was required for public works, tanks, or buildings, "Rajacaria" was, as a matter of course, resorted to. A marked exception to this rule is related of King Tissa, (*q*) who, in A. D. 201, caused the monuments at Anuradhapura to be restored with *paid labour*.

The former production of rice and the decay of irrigation works in Ceylon are thus alluded to in a report of a Committee of the Legislative Council of that island in 1867:—(*r*)

"At a period long anterior to European intercourse with the East, Ceylon, under the rule of its native sovereigns produced rice sufficient to support a resident population, far more numerous than it possesses at present. Of the extent of that population, and of the amount of grain required for their consumption, some general idea may be formed from the many remains of extensive irrigation works to be met with in almost every district of the island. To what degree these works, initiated for purposes of national utility, may have become the mere monuments of regal ambition, it is not necessary to inquire but it is indisputable that the Sinhalese monarchs vied with each other in the construction of irrigation works, and in giving every possible encouragement to agricultural enterprise. Vast tracts of country, now covered with the vegetation of centuries, once abounded in grain. The district of Pomparipo, in the north-western province, yields at the present time but a scanty and uncertain return to the husbandman; yet its name, signifying 'The Golden Plains,' is indicative of the bountiful harvests it once produced. In like manner the district of the Seven Korles was known in ancient times as the 'Granary of the Kandian Kings.'

"The epoch at which the larger irrigation works of this island fell into disrepair, and the causes of their abandonment, are subjects which scarcely belong to the present inquiry, but it is worthy of record that the period most fruitful in disaster to these works, within modern times, was coincident with the abolition of 'Rajacaria,' or about thirty years ago. (That is, forty-seven years from this present date.)

"However opposed to European ideas of social polity, the system of forced labour was not altogether unsuited to the character of the rural population of this island. Its abolition left them freedom, but it gave them no substitute for the system under which the nation had lived from time immemorial. Accustomed to be led like children, and to look up to a strong central influence for guidance and help, they found themselves suddenly deprived of all power of action for the common good. Wanting the strong will which once led them, combination became impracticable. The tanks and water-courses hitherto maintained under the action of 'Rajacaria, were allowed to fall into disrepair. Slight damages were unheeded, and the unfailing influence of successive monsoons rapidly converted small fissures into extensive breaches. Cultivation being thus prevented in consequence of damaged embankments, the impossibility of raising sufficient food on the spot, added to the increasing unhealthiness of the locality, compelled the villagers to disperse, and to seek a scanty subsistence by the production of grain of an unwholesome character."

Probably the last great work undertaken by "Rajacaria" was the road constructed for military purposes, from Colombo to Kandy, and completed in 1831.

On this a certain number of natives were forced to work for a week at a time, strict care being taken that they were fed and fairly paid for their labour.

By an order in Council, dated April 12th, 1832, "Rajacaria" was abolished, and slavery, which for ages had existed as an "abstract right, but mitigated for many years in the forms of its practical enforcement," ceased, in December 20th, 1844, to exist in Ceylon. (*s*)

Much more can be said in defence of "Rajacaria" than is at first apparent. The natives of the East are very indolent, and in Ceylon they delight to repose all day under the shade of a tree, thus enjoying a terrestrial "Nirwana," that is, a "state of blissful unconsciousness akin to annihilation, which is regarded by Buddhists as the consummation of eternal felicity."

Being incapable of self-government, the natives should be governed as children, patriarchally, by an intelligent and benevolent despotism. Statute labour on the roads, in other words, "Rajacaria," has existed in many countries for centuries, and, as regards the maintenance of roads, it is still in force in Ceylon, where every man, between the ages of eighteen and fifty-five, is compelled to perform per annum six consecutive days' labour on the roads, or to commute the equivalent by a payment of one and one-half or of two rupees.

In the North Central Province the system of "Rajacaria" has been to some extent revived, for the sole and immediate benefit of the persons by whom the forced labour is performed. Every owner of paddy-land is required to give what labour is required for the repair and improvement of the village tank on which the cultivation of his land depends, provided that the labour to be demanded in any one year shall not exceed a certain fixed rate, which is about equivalent to fifteen days' labour for each acre of paddy-land. This labour may be commuted for a payment of 50 cents a day, which is about 30 per cent more than the local price of labour. This system has been found very successful, and the only means of stopping the decay into which the village works had been allowed to fall. The value of the work done

s See ordinance No. xx. of 1841.

on these works from 1874 to 1880 was 597,053 rupees.

There is also a local ordinance which provides for the revival of ancient customs in regard to irrigation, under which owners of paddy land can be compelled to join together for the maintenance of the common works on which the cultivation of their lands depends, and they are fined by a village council for failure to perform their allotted shares of work.

It therefore appears to me quite equitable that the natives, who especially benefit by irrigation works, should, on payment of fair wages, be forced to labour for a short period per annum, either at their construction or maintenance; and I can cite several instances where, for want of this compulsion, and in consequence of the refusal of the Sinhalese villagers to work upon the tanks especially undertaken for their benefit, it was, in 1873, most difficult to complete the works. As a rule, the irrigation works in the Eastern Province were made by the Tamils, inhabiting the Northern Province.

Great distress having frequently occurred from the failure of crops in different parts of the Colony, several ordinances of the Ceylon Legislature respecting irrigation, have at various times been passed, and the following are the general principles on which the ancient tanks are now being restored, or on which new irrigation works are undertaken.

To extend the paddy cultivation, an Ordinance, dated December 31st, 1867, contains, among others, the following provisions respecting "the construction, repair, and improvement of irrigation works":—

(*a*) If, at a meeting, called for that purpose, a majority of the cultivators determined that Government aid was necessary for undertaking any irrigation work, plans and estimates were then prepared, and if a Board, consisting of the Government Agent of the Province, (*t*) the Surveyor-General, and the Director of Public Works, reported that it was advisable to carry out such works, the Governor was empowered to order them to be undertaken.

(*b*) A schedule, containing the details of the acreage benefitted and the names of the proprietors, was prepared; the *estimated cost* of the work, when executed, was to be divided, *pro rata*, by this acreage, and to be repaid to Government by ten equal yearly instalments, ensured by compulsory powers of recovery, the charge, meanwhile, having precedence over all mortgages and encumbrances whatever.

The loss to Government incurred by this system is the following:—

(*a*) The interest on cost of works during the ten years in which the expenditure was being repaid;

(*b*) The cost of maintenance of the works during that period;

(c) The liability of the works, or the risk of any over expenditure on them beyond the amount of the *estimated cost*, which alone could be recovered from the cultivators.

The advantage to Government of this system, beyond the benefits of increased food and the consequent general prosperity of the people, advantages very great in themselves, is the increased tax received on the larger yield of paddy.

The Committee of the Legislative Council, Ceylon, thus allude to these advantages in their report, dated September 18, 1867 (Sessional Paper iv. of 1867, page 8): "The Committee have dwelt at some length upon the depression of agricultural interests, caused by the uncertainty of water supply. They believe that the removal of this uncertainty would act as a great stimulus to native industry, one result of which would be an increasing demand for the Crown lands. The proceeds of the sale of these lands would go towards the recovery of the outlay upon irrigation works, whilst the tithe upon their produce would form a permanent addition to the annual revenue of the Colony. Having in view the facts already detailed, the Committee believe that the repair and restoration of irrigation works, and the consequent extension of cultivation, would materially improve the condition of many native communities. No longer compelled to find unwholesome substitutes for rice, the people would be able at all times to command a sufficient supply of nutritious food, their health would become improved, their physique raised, and they might be fairly expected to show an amount of energy and enterprize which is impossible in their present condition.

"The Committee are unwilling to believe that the benefits of improved means of irrigation will be confined to providing daily means of wholesome food to those who are now unable to command them; they look with confidence to the time when the irrigation works of this island may, by judicious outlay, render the inhabitants less dependent than at present on foreign supplies of food. The imports of rice from India necessitates an annual payment for that grain of upwards of a million sterling,(*u*) a portion of which amount might be retained in the country. It may fairly be anticipated that the retention and circulation, within the island, of money now paid away for imported rice, would not only tend to enrich the people, but would increase the general revenues of the country, by enabling the local producers of rice to become large consumers of other taxable articles."

The customs of the Sinhalese and the cultivation in Ceylon are of a very primitive character; property is equally divided among the heirs, and it is not uncommon to hear of a man possessing the 20th share of a small paddy field, or that proportion of a few coconut trees.

Paddy is always cultivated on land laid out as level as possible in pieces, but, at the same time, in terraces, so that the water may flow from the high pieces down to those on the next level, and so on to the lowest portions; in flat fields these pieces of land are large, with a rise of a few inches in each piece, but in steep fields the pieces are smaller, with a rise of from one to two feet.

When the fields are well saturated with water, buffaloes are turned in to trample them, after which the land is ploughed by buffaloes, and then sown by hand.

No machinery is used in Sinhalese agriculture, the seed is "cast upon the waters," paddy is reaped and winnowed by hand, and threshed, as of old, by the "ox that treadeth out the corn."

Paddy fields are generally private property, but there are also fields which belong in common to certain villages, where the villagers share in the yield according to their labour, from the man, who owning the buffaloes, receives his share for their labour, down to the *dhoby*, who washes the clothes of the villagers!!

The ordinary tax on paddy lands is one-tenth of the yield, and the value of a bushel of paddy may be taken at one rupee. The crop upon unirrigated lands depends chiefly upon the weather; in dry seasons there is frequently no crop, and in wet seasons the crop depends not only on the amount of rain, but on the times at which it falls; whereas with irrigation the crop is not only certain, but much greater; it may safely be taken in Ceylon has always doubled and frequently trebled.

An Ordinance of the Legislature, dated January 15th, 1873, gives the cultivators the option of converting the repayment by ten annual instalments into a charge in perpetuity, fixed at the rate of one rupee

t A Government Agent in Ceylon is the chief official in each Province, whose duties are similar to those of a "Collector" in India.

u The value of rice imported of late years has been about wo millions pounds sterling.

an acre, provided that this sum does not exceed 7½ per cent on the cost of the work, and in some districts this charge is paid in kind.

Under this Act, which is still in force, most of the irrigated districts have converted their annual payments into this fixed charge; in other words for this small payment of one rupee per acre, the Ceylon Government construct and maintain the irrigation works, receiving only in addition the ordinary ten per cent of the value of the paddy crop.

The small amount of this water-rate is remarkable, and very exceptional. (*v*) On the Ganges, Jumna, and Baree-Doab canals, the mean water-rate per acre irrigated is stated to be R2.33, and in Madras it was fixed by Government R6 per acre, even although the ryots were willing to pay as much as R10.

Taking the yield of paddy on unirrigated land at ten bushels per acre, and assuming the increased yield on irrigated land, including a second crop per annum over at least half the acreage, at the moderate increase of threefold, it appears good policy for the Government to expend R50 per acre on irrigation work, as the return will yield fully 5 per cent interest, independent of the valuable indirect benefits of increased prosperity in the district.

Thus fixed charge	R1
Tax on increase of 20-10 bushels paddy at R1	2
Total per acre	R3

Thus leaving 50 cents per acre to meet cost of maintenance of works, beyond the interest 5 per cent on R50. (*w*) See Report of the Assistant Government Agent, Matara, hereafter quoted.)

RAINFALL.—The rainfall is the most important item as regards irrigation works. The minimum in Ceylon is on the sea coast at Mannar, where for seven years, ending 1877, it averaged 32 inches per annum; the maximum is at Padupolla about 2,000 feet above the sea, where the *mean* for nine years ending in 1880 was 224 inches, the maximum in 1880 being 272 inches. In the coffee districts the rainfall varies from 80 to 140 inches per annum; in the irrigation district of the Eastern Province it is about 60 inches, and in that of the Southern Province it is some 85 inches.

Rainfalls from 9 inches to 12 inches during twenty-four hours are not unfrequent all over the island, and a fall of 18 inches in a day has occasionally been registered.

In September 1872, a flood occurred in the neighbourhood of Colombo, covering an area estimated at 700 square miles, (*x*) over which an average of 8 inches of rain fell per day for four consecutive days.

During the north-east and south-west monsoons, each of which lasts about four months, the ground becomes so saturated that all the rainfall may be assumed to run off, and as many of the ancient tanks in India and Ceylon have been breached from insufficient waste weir or overflow, called in Ceylon the "spill," it became of great importance to determine the length of "spill" required for each tank.

To afford a margin of safety, I assumed a rainfall of 1 inch per hour, and regulated the length of the waste weir, so that with this fall the water should not rise more than 2 feet over it.

Thus 1 inch of rain per hour per acre equals 60½ cube feet per minute, and as with a head of 2 feet 605 cube feet are discharged per foot lineal of weir it follows that a foot of weir is sufficient for 10 acres; in other words, each acre of watershed should have one tenth of a foot lineal of waste weir.

The practical difficulty in adopting this rule arose from the labour and expense of ascertaining, in a country frequently flat and covered with thick jungle, the approximate area of the water-shed. Owing to the sudden rise and fall of the rivers or streams leading into the tanks, both occurring in the course of a few hours, it is generally impracticable to gauge the streams with any certainty, especially as the officer in charge has other tanks to supervise, and before he could be called to any one the flood had probably subsided. A margin to meet these contingencies is therefore given to the length of waste weir.

It is satisfactory to add that of the many tanks restored during the last ten years only four have suffered from insufficient waste weir; that three of these casualties occurred during an extraordinary flood, (*y*) such as had not been known for fifty years; and that in one case there had been a rainfall of 42 inches during the month, and of 12 inches during the twenty-four hours preceding the breach in the dam.

Rain gauges are kept at each tank, and the height of the water over the sill and under or over the waste weir is registered daily, but a certain distrust exists as to the accuracy of the measurements taken by the native overseers.

The mean evaporation in Colombo for the last eleven years has averaged ·212 inches per day, the mean degree of humidity of the air during that period was 75, complete saturation being 100.

QUANTITY OF WATER REQUIRED PER CROP.—It is calculated in Madras that for paddy cultivation a cubic yard of water is required for every square yard of land to be irrigated constantly throughout the year. This quantity, which equals cube yards 4,840, or say cube yards 5,000 per acre, is generally considered sufficient.

In the Southern Province of Ceylon, where the drought is by no means so continuous as in India, the tanks being replenished during the dry season, half this quantity is ample for one crop, and two crops are usually raised there per annum, the "yala" crop being the largest.

Three special waterings are usually given, the sufficiency of the first and last waterings being the most important, as in default of the first watering the crop will not germinate, and for want of the last it will not mature.

In the Eastern Province, where the rain, which falls chiefly during the north-east monsoon, is about 60 in. per annum, the depth of water required for a crop is said to be about 36 in., and as only one crop per annum is grown in this district, the yield on irrigated land is from twice to two and a-half times that produced on unirrigated land. This return would, however, pay five per cent. on an expenditure of fully R30 per acre irrigated, and the market value of land irrigated as compared with that *un*irrigated has increased in the same proportion as the yield. (Report of the Government Agent, Eastern Province, hereafter quoted.)

In the Southern Province it requires 3 inches of water to prepare the ground for sowing, then about 10 inches during the first two months, and finally about 11 inches more to mature the crop, say 24 inches in all, but of this quantity 12 inches is usually supplied by rainfall.

VILLAGE TANKS IN THE NORTH CENTRAL PROVINCE.—The earthwork required for village tanks is done by the cultivators themselves, each man working, without remuneration, for 30 days per annum until the part-

v Proceedings of Inst. of C. E., vol. xxxiii. pp. 386, 418, 423; also Roorkee, "Treatise of Civil Engineering," 2nd edition, vol. ii. art. 680.

w Ceylon Administration Report, Southern Province, for 1879, p. 138.

y See Sessional Paper xvi. of 1878, pp. 9 and 11.

icular tank with which he is connected is completed; on the other hand, the Government provide and construct, free of cost to the village, the ironwork and masonry required for the sluice and waste weir. No water-rate is charged on lands irrigated under this system.

The repairs of these village tanks were commenced in 1874, and the following is the result of the work done to them up to end of 1881:—

Number of tanks provided with sluices	199
Number of sluices constructed	206
Number of permanent "spills" or waste weirs *constructed*	53
Total cost of sluices and "spills"	R259,785
Average cost of sluices and "spills" per tank	„ 1,305

The number of tanks on which the villagers worked, chiefly in forming and strengthening the dams in 1881, was 912.

The quantity of earthwork thus executed from 1874 to 1881 inclusive was cube yards 2,574,474, and its value, at 30 cents per cube yard, amounted to R772,342. (*z*)

Alluding to the village tanks restored in the North-Central Province, the Government Agent thus writes in his Administration Report for 1878: "As shown in the earlier part of this report, the Government has provided 117 tanks with the necessary masonry works in sluices and spill waters at a cost of 136,988 rupees, or at an average cost for each tank of 1,170 rupees. The people, by whom the restoration of the embankments is undertaken, have worked on 856 tanks, and the value of the earthwork done by them is computed at 387,410 rupees. The earthwork necessary for the complete repair of each village tank is estimated at 3,200 rupees, or about three times the value of the masonry contributed by Government. As the work done by the people is spread over not less than seven years, no village tank, except under specially favourable conditions, has as yet been completely restored; but the large additions made to the embankments by the united labour of the landowners have already borne good fruit; it has not only stopped the process of decay and ruin which threatened to destroy the whole of the ancient irrigation works of this great tank country, but it has given a great impulse to cultivation; has enabled the tanks to withstand floods; has doubled the price of land; has enabled the people to cultivate annually a far larger portion of the existing fields than has been possible within human memory, and gives immediate promise of a large increase in the area of land brought under cultivation. The restoration of the village tanks, even though as yet incomplete, has secured to Nuwara Kalawiya in 1878 the finest paddy harvest ever known, under conditions which before the work of restoration commenced resulted in total failure of paddy cultivation. In the former weak state of the bunds, a heavy flood breached almost every tank, and left the people as entirely without water as if there had been a total drought; but in the great floods of December, 1877, it was found that the tanks, with only a very few exceptions had been so far improved as to hold up a quantity of water larger than they had ever contained before within living memory, without being breached; and the result was the largest crop and the largest land revenue ever known; while in the adjoining districts of North Matale, under similar conditions of life and cultivation, but without any attempt having been made to restore the tanks, all the tanks were breached and there was no cultivation. Though the extent of cultivated land has not yet materially increased, greater security has been given generally to cultivation by the improved state of the tanks, and there is a marked increase in the extent of the existing fields which is cultivated whenever there is sufficient rain to fill the tanks, and also a marked increase in the paddy revenue as shown by the following statement for the five years during which the province has existed.

"Paddy revenue for the five years 1874-1878, showing also the extent sown and the produce:—

	1874.	1875.	1876.	1177.	1878
	Pelas. (*aa*)	Pelas.	Pelas.	Pelas.	Pelas
Extent sown in Pela...	2,277	13,740	20,910	5,974	21,104
Produce in Pela ...	17,745	112,490	142,740	42,143	164,594
	R.	R.	R.	R.	R.
Revenue in Rupees...	11,963	28,583	31,959	18,065	44,732

"From the time known as the British accession in 1815 down to 1874, a period of sixty years, the district of Nuwara Kalawiya was entirely neglected, and the tanks had fallen into such a ruinous state that they barely sufficed to hold up enough water for half of the existing fields. Gradually, as the work of restoration progresses, they hold more and more water, and the extent of the original fields, which can be sown with security, increases accordingly, with the satisfactory results shown in the statement given above. As soon as the restoration has gone so far as to provide more water than is necessary for the existing fields, there will be a general demand for additional land to be brought into cultivation. The present gain is in the greater extent of the existing fields which can be cultivated, and the greater security attending the cultivation by the diminished risk of loss of water, which was formerly of frequent occurrence, owing to the ruined state of the bunds. The bad harvest of 1874 and 1877 were the result of insufficient rainfall to fill the tanks. In like manner, the distress of the present year is caused by the general failure, not only of the paddy harvests, but of all the winter crops, owing to the failure of the usual rains in the last quarter of 1878 and January of this year. When with sufficient water the tanks, even in their partially restored state, enable the people to raise such crops as those of 1878, and bringing in so largely increased a revenue as is shown by the foregoing statement, the argument in favour of not leaving any tanks dependent on rain supply when there exists the means of filling them from rivers, is exceedingly strong; and it may be well here to repeat what is stated in the Annual Report for 1876, that:—'Though the importance of repairing the tanks, so that they may store as much as possible of the rain that falls, cannot, perhaps, be over-rated, still it is not of less importance to the progress and prosperity of this province to endeavour to utilize the rivers which now run to waste, and render the people independent, to a great extent, of the local rainfall, which is uncertain, and generally insufficient.' . . . .

"Deficient rainfall means deficient crops, and it is to be hoped that the Government will not longer delay the restoration of the magnificent canals and river-fed tanks of supply which will render cultivation no longer precarious, but will bring to it the security of an increasing supply of water, such as it possessed under the rule of the Sinhalese Kings. It is on the restoration of these large artificial lakes, and their connected network of canals, that 'the future prosperity of this province mainly depends; and, until they are restored, the Government cannot expect to receive any large return for the large outlay incurred on roads and other public works.'"

MAINTENANCE AND DISTRIBUTION OF WATER.—The maintenance of the irrigation works pertains to the Public Works Department and they are under the immediate charge of the superintending officer of the district in which they are situated. Under this officer, an overseer, with some coolies, has charge of each tank or irrigation work, for its maintenance

z Administration Report, North Central Province, by Government Agent, for 1881.

aa pela is an area of about half an acre.

and for the distribution of water. Ordinary maintenance of tanks consists chiefly in repairing slight settlements or slips, including the damages done by the trespass of cattle or of wild animals; also, in cutting out ant hills and in repairing the damages done by the "burrowing" of alligators in the dams.

On the application of the Government Agent or of the village authorities, the overseer opens the sluice so as to discharge the water required for the given time, and he is held responsible for reporting to the Public Works officer any damage which may occur to the works, and for taking every precaution for their safety.

The duties of overseers in charge of irrigation works are clearly defined in the Public Works instructions; but however full and advisable the rules may be, great difficulty is found in getting them intelligently and faithfully carried out by natives.

With a few exceptions, the superintendence of irrigation works devolves upon the Public Works officer of the district, *in addition* to his ordinary duties of constructing any new roads, new buildings or special repairs of those works which may be on hand at the time. The irrigation works being frequently in remote districts difficult of access, the superintendence is sometimes inadequate.

To prevent waste of water and jobbery in its distribution, as well as to exercise efficient supervision over the maintenance of the works, each irrigated district should be under charge of an experienced European officer, whose sole time should be devoted to the duties. I am confident that the cost of this arrangement would be but a small percentage of the pecuniary saving which it would produce.

The following is a statement of the completed irrigation works, excluding village tanks which have been undertaken, according to the terms of the ordinances alluded to, from 1868 to July 1st 1881 (from a return by the Director of Public Works, Ceylon, dated January 27th, 1882):—

Name o Province.	No. of Irrigation Works.	Estimated acreage capable of Irrigation.	Actual Expenditure.	Average cost per estimated acre capable of Irrigation.
		Acres.	R.	R.
Northern Province.....	1	200	10,808	54·04
North-Central Proninee(*bb*)	3	2,300	176,367	76·68
Central „	8	7,730	89,528	11·58
North-Western „	9	5,460	220,299	40·34
Western „	12	1,577	37,571	23·82
Eastern „	22	57,070	810,939	14·20
Southern „	24	15,731	738,718	56·17
Totals	..79	90,068	2,129,230	23·64

From the above it will be seen that, taken by provinces, the minimum cost of irrigation works per estimated acre capable of irrigation has been approximately ..... R11·58

The maximum cost..... „ 76·68

And the average cost per acre..... „ 23·64

The above figures are approximate, as there is much difficulty in arriving, correctly, at the acreage which can practically be irrigated; for this depends not only upon the acreage which lies under a tank, and upon the rainfall necessary to fill the tanks in the first instance, but upon the rain, which may more or less replenish the tank or river during the dry season. The acreage irrigated also depends upon the care with which the water is husbanded and distributed; unfortunately, in general, much water is wasted. In recording the acreage capable of irrigation, the lowest figures given in the official returns have invariably been taken.

Including the cost of village tanks previously alluded to, the total expenditure on irrigation works in Ceylon from 1868 to 1880, both inclusive, has been as follows:—

Amount of Irrigation Vote including Maintenance.	Amount expended on Construction including Salaries Allowances, and cost of Surveys.	Amount expended on Maintenance.	Total Expenditure.
R.	R.	R.	R.
3,773,321	3,082,618	237,761	3,320,379
Averages per annum 290,255	237,124	18,289	255,413

From 1868 (*cc*) to 1st August 1878, the irrigation works should be credited with the following sums in addition to the value of 10 per cent on the increased yield of the paddy crop, which, as before mentioned has always been doubled, and frequently trebled.

	R.
Amount realized by sale of Government land, which otherwise would probably have remained unsold	312,814
Amount realized by water rate.....	116,080
Amount due on water rate, the payment of which for various reasons had been delayed.....	246,447
	R675.341

If this sum be deducted from the total expenditure on irrigation, R3,320,379, the balance as the cost of the works up to the end of 1880 would be R2,645,038.

The Commission appointed by the Ceylon Government to "enquire into the taxes on home-grown grain and the Customs duties on imported grain," reported on 30th October 1877, as follows (*dd*):—"The policy we would recommend is not to remit or materially reduce taxation, but to make rice cheaper by extending and improving the communications by road and railway throughout the whole interior of the island, and by restoring and improving irrigation works with a view to increasing the local production of grain. The success of the irrigation works in the Eastern Province shows that this is the true policy. The restoration of those words was commenced twenty years ago by Sir Henry Ward, and was continued by Sir Hercules Robinson, and it is the only part of the island where sufficient time has elapsed to render it possible to judge of the results. Thousands of acres, of which 24,000 are in one block, have now been converted from forest and jungle into productive paddy fields, the owners of which are able to send large quantities of surplus grain to Jaffna and Badulla, and other parts of the island. There is every reason to anticipate similar results from following the same policy in other parts of the island, and in order that the Government may be able to do more and not less than it has

bb The average in the North-Central Province is unduly high, as the expenditure on the 13½ miles of the Yodi Ela channel is included, while the acreage is only partly shown. A further length of 40 miles of channel and the head works have to be completed; the work is then estimated to irrigate 500 acres per mile, that is about 25,000 acres at a cost of R545,500 which gives an average of R21·8 per acre, and including the two works Bassawakkulam and Maha Madawachchiya the total will be about 26,000 acres, at a total cost of R632,435, giving an average of R24·3 per acre. The Bassawakkulam tank at Anuradhpura, repaired at a cost of R60,705 and the tank at Vavuniya Vilankulam, in the Northern Province, the cost of which was R10,808 were undertaken more to obtain a water supply for those stations than for purposes of irrigation

cc Ceylon Sessional paper, No. 38, of 1879.

dd See Ceylon Sessional Paper, No. xvi., of 1877.

hitherto done in this direction, we should wish to see the revenues increased and not diminished."

Finally, the Commissioners thus express their views as to the importance of extending reproductive works :—

"The great object for the Government to accomplish is to make the country produce enough grain for its native and immigrant population, and to accomplish this it is desirable to continue on a larger scale than hitherto the restoration and improvement of irrigation works throughout the country.

"It is more to the interest both of the native population and of the European planter to extend the irrigation and to improve the means of communication between the coast and the interior, and throughout the interior of the island, than to reduce taxation."

It is interesting to record that from 1865 to the end of 1871, when the revenue of the Colony did not exceed R11,000,000 per annum, the sum voted for the public works of the island amounted to R24,992,010, (*ee*) or an average for the seven years of R3,570,287 per annum, and that during the next six years up to the end of 1877, with an income never exceeding R14,676,000 per annum, the votes for public works amounted to R22,340,096, (*ff*) or an average of R3,723,349 per annum.

The largest expenditure of the Public Works Department was in 1878, when it amounted to R5,553,638, (*gg*) and for the five years from 1875 to 1879 inclusive, it averaged R4,884,263 per annum.

It was during the administration of the late Sir Henry Ward, from 1855 to 1860, that a liberal expenditure on reproductive works was first sanctioned, a policy which has "resulted in the expansion of agriculture and trade, and in the improvement of the public revenue."

This wise policy is still followed, and for the last twenty-five years the greater portion if not the whole surplus of the revenue over the fixed expenditure of Ceylon has been devoted to reproductive works, viz., new roads and bridges, new buildings, irrigation works, and the repairs of these several works.

This expenditure is altogether distinct from that on the Railway extensions, Colombo Harbour and Colombo Water Works, the cost of which are defrayed from loans raised on debentures.

In the Administration Report of the Public Works Department for 1880 the Director, Mr. Churchill, writes : "As remarked in previous annual reports, the expenditure on irrigation is proving most remunerative and beneficial. In the Eastern Province, by the erection of the anicuts and supply channels, perfect control is obtained over the rivers, the surplus waters of which are stored during the floods and distributed, during the cultivating season, over the vast tracts of land now brought into cultivation, and admitting of even a second crop being grown during the dry season by the aid of the flood water stored in the tanks.

"The same good result is also to be seen in all the other provinces where irrigation works have been carried out.

"A survey and examination is being made of the ancient irrigation works in the Mannar districts of the Northern Province, which centuries ago was one of the great rice-producing districts of Ceylon. So far as they have gone, these surveys tend to show that these ancient works can be restored, and the new waste lands be made as productive and remunerative as of old.

The cost of the maintenance of the irrigation works for the years 1878, 1879 and 1880, averaged R33,147 per annum, or about 1 per cent of their total cost.

GENERAL RESULTS.—The irrigation works referred to having been so recently completed, there has not yet been time sufficient to show their full results; they have also been constructed too much individually, or as separate works, instead of being, as in many cases practicable, grouped together and carried out as one system.

In the Revenue Administration Reports for 1879, the Government Agents writes as follows :—

"EASTERN PROVINCE.—*Irrigation.*—Under this head I have to notice that the southern pattus of Batticaloa district have further cause to be thankful to Government, in that their wants have not been lost sight of, notwithstanding the unforeseen additional expenditure called out by the destructive work of the flood of 1878, and in the face of a declining revenue, as I said before. The irrigation scheme is being steadily proceeded with year by year. Last year witnessed the construction and improvement of anicuts, sluices, &c., benefitting thousands of acres, such as those at Kahyodai, Aladiyodai, and Suriyadi, &c., while of the works for this year, already in progress at the time of writing, two large ones, the Pattamputti anicut and the storage channel for Irakkamam tank, will be available before the year closes."

Similarly the Government Agent North-Western Province reports :—

"There can be no question of the usefulness of the restoration of the village tanks. By providing sluices, which the Government supplies free of charge, the injurious practice of cutting the bund is rendered unnecessary, and by the raising and repair of the bunds (which the villagers undertake) the tanks are made to hold more water, and the cultivation of the fields under them becomes less precarious. It would also be undoubtedly useful to the people, and profitable to the Government, to undertake the restoration of large tanks, which, though now breached, would if repaired give an assured supply of water to fields already under cultivation. There are several such tanks in the province, but the best of them is Pandawewa, which is situated in a part of the Dewamedi Hatpattu, where three out of five crops fail for want of water. The tank is said to have been built be Panduwasa, the second King of Ceylon. There are the ruins of an ancient city close to the end of the bund. The tank was last breached about eighty years ago. It is fed by the Kalamunu-oya, a stream which drains a large extent of country, and would constantly replenish the stock of water. The area of the tank, when restored, will be nearly 1,400 acres, and it will irrigate about 2,500 acres. . . . . I only hope that the cost will not be prohibitive, and that the work of restoration will be one of the works to be undertaken under the irrigation vote of next year. That it will be of incalculable benefit to the people I am thoroughly convinced."

In the Administration Report for 1880, the Assistant Government Agent of the Southern Province writes :—

"The Tissamaharama irrigation scheme promises exceedingly well, and I believe will amply repay all the money that has been spent upon it. The expenditure up to date has been approximately R142,000, and it requires a further outlay of about R60,000 to make provision for meeting the large demand there will soon be for water. . . . . 1,940 acres under the tank have been already sold, realizing a sum of R25,870, and I have received applications for about another 1,000 acres, but the sale of land has been stopped till better arrangements for the supply of water can be made. In anticipation, however, of the completion of the work, I am having 4,000 acres of land cut up for sale, which, when cultivated, will

(*ee*) Address of Governor Sir Hercules Robinson, on closing the Legislative Council of Ceylon on December 29th, 1871.

open the country from the tank to the sea at Kirinda, and make the Magampattu the richest agricultural centre of the province. . . . . I believe that much of the unhealthiness of the locality will disappear as the country is opened up and a regular supply of good water and food is obtained."

The Government Agent, Southern Province, in a letter addressed to the Ceylon Government, dated March 12th, 1880, alludes to Tissamaharama in in the following words :—"I have much pleasure in being able to report that the restoration of this work promises to prove a great success, and fully to justify the expenditure upon it. Nothing could be more gratifying than the sight of the splendid crops on the 200 acres under cultivation at the time of my visit. This extent will be increased to 500 acres in about a couple of years.

"All the land for which there is sufficient water will now undoubtedly sell by degrees, and be brought into cultivation without any attempt at forcing, by forming what have been called 'colonies' or pauper settlements, and without the offer of any more liberal terms than are now accorded under Sir Henry Ward's minute.

"The reclamation of the whole land will no doubt be a work of time, but it will, when accomplished, be a work of the highest benefit, and will materially improve the climate. Already the cleared land is found to be comparatively free from the fever for which the place is known."

The Assistant Government Agent of the Matara district, Southern Province, gives the following return of irrigation works in that district for the years 1878 and 1879 :—

	1878.	1879.
Acreage irrigated	6,859	6,859
Capital expended ...	R 386,236	386,236
Cost per acre	56·31	56·31
Increased revenue on tithe and water-rate representing interest on expended capital	19,879	18,958
Rate per cent on capital	5·12	4·90

The Assistant Government Agent adds :—"It has only been during 1878 and 1879 that the works have been in full play, and their effect was even then much neutralized by unseasonable floods; but, with every disadvantage, it will be seen that the return on the expended capital for the two years was 5 per cent, and I feel confident that in the future this will be exceeded."

As regards the general advantages of irrigation works and as a means of water supply in the dry districts of Ceylon, irrespective of their benefit to paddy cultivation, the Government Agent of the Northern Province thus writes in his Administration report for 1880 :—

"Irrigation works, as they are termed, seemed to me to be too much considered merely in their connection with paddy cultivation and the effect they would have in increasing the cultivation of paddy. As regards, however, such comparatively rainless districts as those comprising the Northern Province, a broader view should, in my opinion, be taken of them, and the general good which might result from the carrying out of works, which might reasonably be expected to have the effect of increasing the water supply of such districts, should be considered. The storage of water in tanks during the rainy seasons in such districts, as a reserve to fall back on during the dry seasons, instead of allowing it to run to waste as it now does, in consequence of many of the tanks being breached, must have a beneficial effect on the country, irrespective of any good that may result in an increase of paddy cultivation.

"The soil of the Vanni pattus is in many parts rich and fertile, All that is wanted is water, and that, in ordinary seasons, only a few months of the year during the dry season. Anything, therefore, that would give the people supplies of water within reasonable distance of their villages, sufficient for ordinary domestic purposes and for merely keeping alive fruit trees, plants, and vegetables during the dry seasons, or which would enable them to tide over a season of drought, would be a great boon to them."

These reports, made not by any member of the Public Works Department, but by the Chief Revenue officers in each province, clearly show that the irrigation works in Ceylon have proved successful, and it is but reasonable to expect, when longer in operation and when futher developed, that the benefits of irrigation will be much more apparent.

The figures given in this paper are taken from the official reports forwarded to Government; the cost of the works is doubtless correct, and allowing for any probable inaccuracy in the estimated acreage capable of irrigation, the average cost per acre irrigated would not be much increased.

With but two exceptions, the highest cost per acre —R56·17—is in the Southern Province, where, since the works were in "full play," they have paid an interest of five per cent., and since it has been shown that a capital of R50 per acre can be profitably expended on irrigation, it follows that in a few years the Government will reap a very large direct return from the capital spent.

As this capital averages only R23·64 per acre it is evident that a return of even R2 per acre per annum would pay 7½ per cent. on this sum after deducting 1 per cent. for the cost of maintenance and of casual improvements.

The direct return is, however, only a small portion of the benefits resulting from irrigation; whatever may be the cost of these works the followiug are the results :

(*a*) That without irrigation a dry year in many parts of Ceylon means almost famine. (*hh*)

(*b*) That a crop which formerly was doubtful is rendered certain.

(*c*) That the yield is always doubled, and frequently trebled.

(*d*) That comparative plenty succeeds want.

(*e*) That the health of the cultivators is greatly improved.

(*f*) That the population, as shown by the census of 1881, has during the last decade increased in the irrigated districts of the Colony in a much larger proportion than in the *un*-irrigated districts of the same province. (*ii*)

(*g*) That, in fine, the general condition of the people is vastly ameliorated, and that the prosperity of the Colony is increased in proportion.

The object of this paper is to show that these advantages can be secured at a moderate cost, and I hope that the success which has attended the irrigation works in Ceylon may promote similar works in other Colonies.

The works alluded to were principally designed by Major Woodward, R.E., who for nine years held the post of Irrigation Assistant in the Public Works Department of Ceylon, and they were executed by the various officers of the department in whose districts they were situated, but especially by Mr. J. F. Churchill, Mr. Robert MacBride, and Mr. James Arneil, Members of the Institution of Civil Engineers. I have not attempted to describe the construction of these works in detail, as such particulars would be too technical for an unprofessional audience.

---

hh Administration Report for North Central Province for 1878, p. 107.

ii "Ceylon Government Gazette," July 22nd, 1881, p. 126

The CHAIRMAN (Sir John Coode): Before calling upon the several gentlemeu who have kindly undertaken to address us, I may, perhaps, be permitted to offer a word or two, by way of comment, on the valuable paper we have just heard read. When I call your attention to the fact that the works Mr. Mosse has described were for the most part constructed something like 2,000 years ago broadly speaking, you will, I think, agree with me that very considerable historical interest attaches to them. (Hear, hear.) Mr. Mosse tells us of a dam 11 miles long and in some places 70 feet high—the Padivil Tank. He then tells us of the Kalawewa Tank, which is about 40 miles in circuit: the dam in this case averages 60 feet high, and is about 5½ miles in length. He further tells us of another dam—the Karaganga, a huge embankment ranging from 40 to 90 feet high, and for many miles averaging 80 feet high, and continued without intermission a distance of 24 miles. These are works of great magnitude, and that they should have been constructed for such a purpose and at such a period is to me a matter of considerable historical interest, as I think it must be to all present this evening. Again, from what I may call the politico-economical point of view, these works are very important. Mr. Mosse has just told you, briefly and concisely under seven different heads, what the results have been. The three most important of these are the almost absolute avoidance of famine; the crops formerly doubtful are now rendered certain, the yield being doubled if not trebled; and the health of the cultivators is greatly improved and the condition of the people generally very much ameliorated. These are, I say, most important facts, and I think we are very fortunate in having had them placed before us in such an able manner by Mr. Mosse. (Hear, hear.) Ceylon is a country not always blessed with those "spicy breezes" of which we have all heard. It is subject not only to occasional deficiency of rain, but also to floods of a most damaging character. Some eight years ago I was asked by the Government of Ceylon to give them some professional advice with a view to relieve the low-lying districts near the coast of the effects of some of these floods. Perhaps, as Mr. Mosse has been treating on the rainfall in Ceylon, I may be permitted to mention a fact or two concerning it. In the flood of 1837, upwards of 1,200 houses are said to have been destroyed. In the flood of 1834, the damage was even greater than that. As lately as 1872, in some districts, the floods lasted from ten to twenty-one days, and the water rose from 10 to 20 feet—in some instances as high as 30 feet. One official reported that in part of his district the water rose so rapidly that the inhabitants had to be rescued in the night through the roofs of their houses, that on that occasion more than 350 villages were considerably flooded, and that in one district alone 541 houses were destroyed. These facts illustrate the violent changes of climate in Ceylon. They show what the people are subject to in the island. I am glad Mr. Mosse has put before us such a practical paper this evening. The information it contains will not be confined to those now present. The paper and the discussion will be carried, I may say, without exaggeration, to the uttermost parts of the earth, and the Royal Colonial Institute, in affording the means of eliciting, and in bringing before the public in general, and colonists in particular, the information the paper contains, and such further information as will be given in the discussion, will be fulfilling one of the most important functions for which it was established. (Applause.)

The Right Hon. Sir WILLIAM GREGORY, K. C. M. G.: I think the Paper which has just been read by Mr. Mosse is a valuable Paper. It contains a good deal of statistics, which may perhaps be considered heavy reading, but they are extremely valuable to any person who wishes to consult the Paper for information. In various countries information is being sought on the subject of irrigation. It is not merely in Ceylon and in what I may, call our tropical colonies that the subject possesses interest but in Australia I have had many inquiries made to me on the subject of irrigation from tanks, and I have been asked repeatedly by Australians to give them information upon the working of our system in Ceylon, for in Australia, as you are well aware what they suffer from is drought at one time and floods at the other, and they think that if some such system could be carried out in parts of Australia as prevails in Ceylon the surplus water which now runs to waste might be stored and the country be greatly benefitted. Permit me to mention one or two facts in respect to the effects of irrigation. When I went to Ceylon in 1872 I visited the Eastern Province, where irrigation works were begun by Sir Henry Ward and carried on by Sir Hercules Robinson. In those days I did not know much about the mysteries of tanks, spills, anicuts, etc., but there were certain facts which struck me. I saw standing on one height an expanse of 24,000 acres—waving green in paddy. The charred stumps of trees and logs lying about showed that only a very short time previously this tract had been a jungle. Surrounding this vast expanse, converted from jungle into land producing human food, I saw a large, well-fed, contented population, with children bright and gay and round and plump, and I came away with the impression that there was great prosperity surrounding those irrigation works. A few months afterwards I went up into the north and middle portion of Ceylon—a vast district very little known in those days, and which no Governor of Ceylon had visited for a space of sixteen years. The contrast was very remarkable. I saw a poor, downcast population—a people who, apparently, had resigned all hope. If I may make use of a strong expression, they were rotting away by disease, and almost perishing by famine. They were always in danger of dying by famine, and absolutely the greater part of the country was being decimated by disease. I passed through a district a little north of this large tract of country of which I am speaking. I saw villages, or what were villages a few years before, for the palm trees were there, and I asked what had become of the people. "Oh, dead or run away." That was the state of that country under English rule. It was a country eminently fitted for irrigation. In the district to which I allude the report of the Government Agent of the province for 1871 mentions that there were 1,600 village tanks belonging to 1,500 and odd villages, and that not a single one of them had sluices, or was capable of containing water to any extent. We have ample confirmation of the former fertility of that great tract of country, for we have an account in 1678 by the English prisoner Knox, of the central city of Anuradhapura being surrounded by a vast and fertile plain, all teeming with plenty. It was perfectly clear that something must be done to remedy this state of things, and the first thing I endeavoured to obtain was a reconstruction of the village tanks. I have not time to enter into particulars, except to say that through the agency of the village councils themselves we were able to set the people to work at their tanks, and that at this moment there are 1,200 out of the 1,500 tanks being repaired, a large number of which are already so far completed that sluices are put into them. So far from the people being subject to want and periodical famine, the price of rice has fallen from 1·50c and 2·50c per bushel to 50c; and they have not only ample food themselves, but are exporting large quantities of their produce to the north of the island, and receiving other commodities in return. (Hear, hear.) I never saw such a revival in the whole course of my life. I have quite recently been there, and I saw large tracts which were almost impenetrable jungles now waving under rice. (Hear, hear.) Not only that, but this terrible disease which has been extirpating the population of the country has been arrested completely. At one time ward after ward was being constructed, in which to place those suffering from disease, and now, according to the reports of the principal medical officer and of the medical officers of the country, there are hardly any inmates of those wards. As the ablest and most sensible of the medical men said, "Medicine can do very little good; food can do a great deal;" and now they had ample food, good water, and good air. (Applause.) I think the way in which we laboured to pull up almost from the very depths of distress a large population of well-conducted fellow-subjects—some 60,000 or 70,000—and to place them on their legs, is no small matter. Even if it had cost a considerable sum of money it would have been no small matter, but I most firmly belive that these proceedings in the way of irrigation will not only be productive of an enormous amount of good to the people, but will eventually amply repay the Government the outlay they have incurred. In the paper just read, Mr Mosse goes down to 1879. A report has appeared within the last few days from the present Government Agent of

the province. Some portions of the report I would like to read, but I will merely state that he shows that, during the last five years—the period in which there has been irrigation—the land which has been cultivated has averaged 11,000 acres per annum, whereas in the five years previously the average was only 3,000 acres; and whilst the average crop in the latter period was only 141,000 bushels, the average crop during the last five years has beeen 288,000 bushels. (Applause.) This is what Mr. Fisher* says:—"As far as we are capable of judging, the action of Government in promoting and persevering in the restoration of these works has been amply justified by results. We have placed at every man's door a superabundance of cheap food and the no less necessary supply of comparatively wholesome water. We have arrested the progress of disease and put new life into the people, and if we persevere in the same line of conduct it is within our compass to place the people of the province permanently beyond the reach of the famines which have afflicted them in past years. The opponents of irrigation allow of none of these things. But they are considerations which it is impossible for any humane government to ignore, and when it is shown that the amelioration of the condition of the people has been attended by beneficial results of such magnitude as the figures in this paper disclose, there can be no hesitation in continuing our efforts to better the condition of the people and country." In conclusion I would say that the work I did was to endeavour to interest every man in the restoration of his own village tank, and the present Governor is taking a more onward and far more important step—viz., endeavouring to restore the great tanks which will contain a permanent store of water, and which water will always be available in time of drought. That is to be effected by damming up the rivers, and at the present moment they are engaged in damming up the great tank of Kalawewa with an embankment 60 feet high and 5 or 6 miles long. This, I believe, will be effected in two or three years, and will give an ample and permanent supply to a series of tanks for a distance of 60 miles. The whole scheme is now being systematically carried out, and I find in every part of the island where the good example has spread exactly the same results, both as regards the health and condition of the people. (Applause.)

Sir JOHN DOUGLAS, K.C.M.G.: Mr. Mosse having, as a professional man, been in charge of large works in Ceylon and elsewhere, naturally views the subject rather from the engineering point of view. My right hon. predecessor and myself naturally view the subject rather from the administrative point of view,—that is to say, what it can do for the people. People who live in England have no idea, or at any rate have the faintest idea, of the importance of rice to the Sinhalese villager. Our agriculturist has beef, mutton, pork, and other kinds of food, as well as bread, but the Sinhalese villager is a Buddhist and a vegetarian, and if he does not get rice he must go and find roots in the forest, something unhealthy and bad for him, to take the place of his ordinary food. In the old days the native rulers, knowing the villager need only work for his own benefit seven or eight months of the year, determined, during the remainder of the year, to organize the labour for the general benefit in constructing receptacles for the water necessary for the cultivation of the fields, and also made rules by which they were obliged to labour for the maintenance of those works. The British Government took over the island of Ceylon at a time when there was a great outcry about slavery, and the statesmen of England, little understanding the situation in Ceylon, but urged by a noble desire to purge the good name of England from the shame which rested upon her in connection with the West Indies, said, "We will have no forced labour in Ceylon." The consequence was that we destroyed at once the whole machinery by which the great works of the Kandyan kings were kept up; one by one they became neglected and breached, and the people were reduced to the condition so graphically described by Sir William Gregory. We have lately found that it is consonant with the feelings and traditions of the people to work for their own benefit on an organized system, under rules which they make in their own villages, according to their native customs, and the result has been the improvement in their condition which Sir William Gregory so forcibly described. But there is something more than food; there is drink. The Sinhalese villager is a water drinker, and, if he is to continue to be a healthy man, must have wholesome water. Some fourteen years ago I was staying at a small village in Ceylon. It was the dry season. Outside the house was a tank, which was dried up till there was a little pool about half the size of this room, and about two feet deep. The buffaloes were wallowing in the mud. This was the water the people had to drink. I asked for some water for a bath, and the people laughed. They said I might get some six miles off, and we sent the six miles. It was so bad that, after being filtered six times through some towels, it smelled so nasty that I opened three bottles of soda water and washed my hands and face in that. (Laughter.) It was very nice, but decidedly expensive, and certainly beyond the resources of a Sinhalese villager. When the people were reduced to bad food and drinking water, such as I have described, can you wonder that they should die out steadily? I went through the same country last November, and again in January of the present year. I never saw such a striking contrast in the condition of a people. The fever seemed to have departed. The people were all fed and fat; instead of having a scarcity of food they were able, as Sir Wm. Gregory has said, to export food to other parts of the island. (Hear, hear.) I do not pretend to say we have not had to buy our experience. When we began these irrigation works we got skilled gentlemen out from England, who had an idea that these Kandian kings, not having been apprenticed to any great engineering genius in England—(laughter)—knew nothing about the subject, and they said, "Oh, these men, what could they know; they were all wrong, and what we have got to do is first to revolutionize everything." The result was that some of our skilled engineers began to make water run uphill, and do things of that sort, and for the last fifteen or twenty years we have been finding out that after all the Kandyan kings knew a great deal about the matter, a great deal more than we did. Unfortunately, they had not the appliances recent discoveries have placed at our disposal to enable them to try to regulate the distribution of the water; but they had a very good idea of making the water run downhill, and we have found out what wise men they were, and how well they understood how to supply the country with water on the principles of common sense. (Hear, hear, and laughter.) At this late hour I will not detain you, when there are other gentlemen anxious to address the meeting, but I will say that, from my point of view and from the point of view of Sir Wm. Gregory, we cordially endorse what Mr. Mosse has said about the importance of going on with the good work begun of late years. It was begun by Sir Henry Ward; it suffered stoppage for a time; it was taken up again by Sir Hereules Robinson, and after him by Sir Wm. Gregory. Mistakes we have made, and we have found out, I hope, how to avoid making mistakes in future, but, having bought our experience, I think we ought to profit by it, and go on with the good work which has been so well inaugurated and carried out by Sir Wm. Gregory during his term of office. (Applause.)

Mr. J. FERGUSON: You have heard an interesting account of ancient and modern irrigation works in Ceylon by Mr. Mosse, who has considered the subject from the engineer's point of view, and you have had the advantage of learning the views and experiences of a former Governor and the present Lieut.-Governor of Ceylon in Sir Wm. Gregory and Sir John Douglas, who represent official authority. I am neither engineer nor administrator, but would endeavour to give you, as a humble representative, some of the views of the unofficial community of Ceylon, and my own impressions on the subject of irrigation after 23 years' residence in that island. Mr. Mosse has, undoubtedly, given a good deal of technica and statistical information, which ought to be of use in other colonies where irrigation is of importance, provided the peculiar conditions of Ceylon—lying in the pathway of the two monsoons, and with its generally abundant rainfall—is borne in mind. But I cannot enter on technical points, although there are a few unimportant corrections or additions I would offer to Mr. Mosse. I concur in the credit to be given to the Ceylon Public Works Department for their execution of different irrigation works more especially of recent years, and would add, among others, the names

* Memorandum on the Results of Irrigation in the North West Province, by Mr. F. C. Fisher, Government Agent, dated Anuradhapura, 15th December 1883.

of Messrs. Vine and Primo to those already mentioned, as able executive officers who have done good service in this branch. Mr. Mosse remarks on the "very indolent" character of the natives of the East, in sleeping so much during the daytime; but in respect of rice cultivation, I cannot forget a discussion in the time of Sir Hercules Robinson, when the late Mr. James Alwis and the Hon. Mr. Dias, now Judge of the Supreme Court, both Sinhalese of high family, conclusively demonstrated that the Europeans were liable to misjudge the Sinhalese, who took their siestas under trees and in their huts, while the colonists and their coolies were at work, because these men often worked in their houses or fields, and watched their crops for a great part of the night, which is, indeed, the favourite time for working or travelling with many natives. As regards "the subdivision of property," referred to by Mr. Mosse, the illustrations he gives are moderate when contrasted with some known in our courts of law, where the evils of this system have been shown by a claim for as low as the 2,520th part of 10 coconut trees! Next Mr. Mosse mentions that "no machinery" is used in agricultural operations in Ceylon. Well, it is right to mention that experiments have been made from time to time in this direction, and I remember the trouble taken by Mr. Elliott, C. C. S., when in charge of the Matara district, and how he got some of the Sinhalese farmers interested in ploughs, winnowers, and threshing machines, but, I fear, without their use being permanently continued. In conversation, the other day, with Mr. James Howard, M.P. (head of the great Bedford agricultural machine manufactory) I found that, after considerable attention, his firm had * found India a very promising field for the introduction of implements; but Mr. Robertson, of the Madras Agricultural Department, has successfully introduced Norwegian ploughs and some other improvements. When travelling in the United States, through the Carolinas, Georgia, and Florida, a few weeks ago, I was much struck with the one-horse, or rather one-mule, ploughs and other implements used by the negros in cultivating their little farms, the soil being very light, and I have no doubt that the present energetic Director of Public Instruction in Ceylon (Mr. Green, C. C. S.), who is taking a warm interest in agricultural improvements, will gain more from America than Europe in the way of suitable agricultural implements for the natives. I am glad to see Mr. Mosse emphasising the fact that a much lower water-rate is paid by cultivators in Ceylon than in India, as misapprehension has existed on this point; but at the same time the rice crops on the Indian continent are far heavier—as I will show by-and-bye—than in our island. Mr. Mosse, however, makes out too good a case in his figures when he takes credit not only for 116,000 rupees paid water-rate, but for 246,000 rupees not paid, but still due. I suspect a good deal of the latter will have to be struck off by the Government. And now, having offered these corrections, I would guard against certain wrong "inferences" which a stranger, unacquainted with Ceylon and its industries, its climate and soil, might be led into from perusing Mr. Mosse's Paper. I do not blame Mr. Mosse in the least; he has kept strictly to his subject of irrigation; but, as this is the first Paper on Ceylon which has been read at an Institute meeting for a long time, and as the present is peculiarly a time when the resources and industries of our island ought to be understood, I hope I may be pardoned for criticising, and perhaps travelling a little beyond the bounds of Mr. Mosse's Paper:—(1) It must not be supposed by outsiders that, although Mr. Mosse alludes to no failures or mistakes, none have been made in the construction and restoration of irrigation works in Ceylon during the last thirty years. Mistakes of policy, engineering blunders, great excess of expenditure over estimates, have not been unknown to us in Ceylon, as a study of official papers will show. At the opening of his paper, Mr. Mosse alluded to vast irrigation works being formed in ancient days, "to enrich the lands of Buddhist temples." He might have safely added that many of the big tanks had for their *raison d'être* the exaltation of the name and fame of the despotic kings who were able by a word to compel thousands of their subjects to labour on them for months, and perhaps years.

* The "but" which follows suggests the idea that a "not" has been omitted here.—ED.

Now this natural craving after notoriety among men wielding authority has, in the opinion of the colonists and intelligent independent natives of Ceylon, not been unknown among our English Governors, colonial secretaries and engineers—(hear, hear, and laughter)—often anxious to leave their mark on the island by something more prominent than village sluices or channels—namely, the restoration of one or other of the big old tanks—without duly weighing the cost, or the absence of the conditions in surrounding population, able and willing to do justice to the water supply so provided. Sir Hercules Robinson laid down the sound test—"Will it pay?"—in reference to works proposed out of the public revenue, and Sir William Gregory, as a rule, followed his example; but there are a few big irrigation works of able Governors since 1856 which can scarcely be said to have answered expectations, and on which at this moment most people in Ceylon believe public revenue was prematurely expended. A splendid tank surrounded by desirable land may be situated in the midst of an almost depopulated country, and when the work is done the people do not come forward to possess, occupy and utilize. Colonization schemes fail; a limited company collapses, and the lesson would seem to be in respect of similar gigantic undertakings, *Festina lente*. Mr. Mosse quotes with approval Mr. Churchill's report on the Manaar district, where, undoubtedly, there is scope for the expenditure of a great deal of money on irrigation works and their restoration; but caution is very necessary in such a case. Sir Arthur Gordon, as mentioned, has gone in already for a big scheme in the "Kalawewa," and we colonists and the intelligent native taxpayers all hope, rather than fully believe, it may prove as financially successful as Mr. J. F. Dickson, Mr. Fisher, and the other officers concerned, are so sanguine in anticipating. On the other hand, to the restoration of ordinary village sluices, channels and tanks, which can at once be utilized by the people, the unofficial public of Ceylon have ever given the utmost countenance and support, through the press, public bodies, and the Legislative Council. (2) The second wrong "inference" which might be drawn from Mr. Mosse's paper is that rice cultivation in Ceylon is a very profitable industry for the Sinhalese and Tamils. In reality, it is doubtful whether under the most favourable conditions of irrigation, cheap labour and transport, a good market, and light taxation, possible in Ceylon, our cultivators can compete with their brethren on the extensive rich alluvial plains of India and Burmah in the production of rice. Sir C. P. Layard, the most experienced living member of the Ceylon Civil Service, has written on this point:—"The cultivation of paddy (rice) is the least profitable pursuit to which a native can apply himself. It is persevered in from habit, and because the value of time and labour never enters into his calculation. Besides this, agriculture is, in the opinion of a Sinhalese, the most honourable of callings." The average yield per acre of rice in India must be from four to eight times that for Ceylon; of the lesson to be learned from this fact I will treat later on. (3) It might be erroneously supposed that Mr. Mosse attributes the increase of population in Ceylon, the improvement of the people, and the enhanced prosperity of the colony generally, to be dependent on the restoration and construction of irrigation works. Now the one great fact which explains the advance and prosperity of Ceylon and the vast bulk of its people during the last 30 to 40 years is found, not in "irrigation," but in the rise of the planting enterprise, conducted by Europeans and natives alike. To the coffee, palm-tree, and cinnamon industries, but especially to coffee, is directly due the marvellous advance of this colony—a fact which has been admitted over and over again by successive Governors, who have drawn from this source the surplus revenue they were enabled to spend with so much benefit in the poor, sparsely-populated native districts referred to by the two previous speakers. (4) It might be inferred that the Government of Ceylon ought specially to aim at making Ceylon independent of India in respect of the rice supply required by its urban and immigrant population, As well, in my opinion, might Great Britain hope to become independent of foreign grain. No doubt two millions sterling for seven million bushels of rice is a heavy payment for Ceylon to make to India in a year of planting prosperity; but if, as I believe, the rice can be bought more cheaply than it can be produced at home, it is surely wiser in Ceylon to go

on with planting fruit, leaf, oil, fibre, and bark-yielding trees, and in digging plumbago, and so creating wealth through industries for which our island is adapted pre-eminently over most other lands. "Buy in the cheapest, sell in the dearest market" settles the question, and it must be noted that the great import of Indian rice has taken place *pari passu*, with the advance in planting. Thus, 45 years ago, when coffee planting had only begun, less than half-a-million bushels of rice imports into Ceylon sufficed; in 1877, nearly seven million bushels were required, but with the check to coffee (from the dire fungus disease on the coffee leaf), this has now fallen to five million bushels. No doubt there are Sinhalese and Tamils in Ceylon who, if they devoted time and energies which at present are far from being fully utilized, to rice culture, might furnish a larger local supply; but when the emulative spirit and education come to call out the dormant industry of the sections of people referred to, query whether they may not find palms and tea more profitable to cultivate, even if they have to buy their rice. India is likely as time rolls on, to beat America and Australia in the supply of cheap wheat; and when the export duty on her rice is taken off (as was recently hinted at) India is certain to give Ceylon, Mauritius, and even the West Indies, cheaper rice that they can raise, and this fact would, I am sure, be still more fully realized if the so-called "food taxes" in Ceylon (the Customs duty on imports and the rent on rice fields) were both abolished. Inasmuch as this (grain) is the only branch of agriculture in Ceylon on which a direct revenue levy (rent) is made, civil servants, I sometimes think, are apt to overestimate its importance, just as they are obliged to give it so much more of their personal attention. But I hope that both the Government and their officers will realize the vast advantages Ceylon has as a palm, fruit, tea leaf, bark and fibre producing country—the land of spices and tropical products *par excellence*—and will do all in their power to encourage the people in these profitable industrties, while by no means discouraging the rice cultivation to which they are already attached. As regards the occupied, populous districts of Ceylon—the Western, Central, and Southern provinces (Mr. Ferguson here illustrated his remarks on the large map of Ceylon on the wall), in which 2,000,000 out of 2,800,000 of people are found, and over which there is a well distributed and generally abundant rainfall, we have conditions of climate, soil, and transport which point to planting and garden cultivation as more suitable and profitable than rice or other cereal cultivation. Nor can it be denied that the native Sinhalese and Tamils, among whom education is rapidly spreading, have shown any lack of emulation in competing with, or copying the example of, the European planters. The fact that, before the disease-fungus appeared, the natives had increased their export of "*native* coffee" from 10,000 to 220,000 cwt. of coffee in a generation, shows this. The greatly-increased export of cinnamon bark, and of plumbago, almost entirely from native hands, offers other proofs; but still more striking is the enormously developed cultivation of palm trees—more especially of the cocoanut, palmyra, areca, kitool palms—within the past twenty to thirty years. So great is this industry now that it covers a far larger area than rice culture, and if we add in other edible fruits, we get 860,000 acres planted with palms and fruit trees, against 810,000 acres cultivated annually with rice and all other cereals. I fear the Government and Civil servants of Ceylon do not altogether realize that their palm and fruit tree industry is at least of as much importance to the natives of Ceylon as their rice culture. Not only does the former supply an expert trade worth fully 800,000*l.* a year, but the fruits enter very largely into the food of the people; so that while grain is the staple, yet, if rice failed altogether, there are probably large districts in Ceylon in which the natives with their coconut, palmyra and fruit trees, could ward off famine effectually. Tennent mentions a Kandian family in Ambegamua, who supported themselves by the produce of one kitool (*Caryota urens*) tree; and the ownership of ten coco-palms and two jak trees have been counted to render a Sinhalese man independent. A crew of English sailors wrecked on a South Pacific island two years ago lived for some months on nothing but coco-nuts and fish, and gained in weight. Now let me allude to a curious fact to which my attention has only recently been directed. Out of the 5,000 tanks counted in Ceylon in 1867, most of them breached, it is worthy of note that the great Sinhalese king, Prakrama Bahu, of himself, 700 years ago constructed or restored not less than 2,800. Now at this time, 1,153 A. D., the vast proportion of the population of Ceylon was congregated in the north, north-west, and east of Ceylon, perhaps 3 to 4 million of people, where now there are only 800,000, and where large districts lie waste, covered with jungle forest with the remains of these hundreds and thousands of ancient tanks. Now, before the devastations of war had driven the people to the hills and to the south and west, there can be no doubt that the region referred to was admirably adapted for rice culture and irrigation works, and that rice was pre-eminently the (almost the sole) staple, because it is a fact that at that time the coconut and palmyra, or at any rate the coconut palm was practically unknown to the people of Ceylon! No mention is made of it in lists of desirable fruit trees made at that time.* How great the difference now, and how easily may we realize the vast importance of rice at that time to king and people. Now the Jaffna peninsula, in the far north, the north-west, west, and southern coasts, and a few parts of the east coast of Ceylon, form one continuous grove of palm trees, almost entirely owned by natives. Nor are our Sinhalese and Tamils backward to copy the European planters in reference to the new products of late years being introduced into Ceylon. They have gone in for cinchona planting—the complaint being that they too often steal the nursery plants of the colonists—(laughter)—for cacao and even for rubber trees; but especially are the Sinhalese likely to become extensive growers of the tea plant, which flourishes so well from sea level to 6,000 feet high all over the south, west, and centre of Ceylon, that the wonder to us is that we did not all begin tea growing 20 or 30 years earlier, a leaf crop in our Ceylon climate being so much safer and more abundant than one of fruit, such as coffee. Every Government district officer in Ceylon ought to have an experimental garden for new products, to shew and supply to the natives near his kachcheri (office); and Agri-Horticultural Exhibitions with prizes, and fairs (as already begun at Kurunegala), ought to be frequent. I hope it will not be supposed I am under-rating the good done by irrigation, especially in the North-Central, and Eastern provinces. I am only anxious that the Government and public officers should recognize that even here the beneficent revival of "Rajacaria" might be utilized for palm and other fruit-tree planting, as well as for rice,† and to point out the importance of encouraging an industrial movement which already gives Ceylon a crop of over 500 millions of coco and palmyra nuts a year. Mr. Mosse alludes to the fact that the absence of irrigation may, in a year of drought, mean famine to Ceylon and to Indian districts; but I would wish to recall the fact officially proclaimed as showing the value of good cheap means of transport in both countries, namely, that there has never in the year of greatest famine been any lack of food for all its people in India—only, while large districts had a super-abundant crop, others, where the crops failed had not the means in road, railway, or canal of drawing on that surplus which was going to waste, often not far away. As regards Ceylon agriculture, both in the hands of native and European planters, I may safely say that never did it occupy a sounder position in itself than to-day; for, apart from rice and palms, we have now three established staples—tea, cacao, cinchona—and two or three more—rubber, new spices, &c.—in an experimental stage, where but a few years ago we had only the one namely, coffee. Better prospects are before this last-mentioned staple this year; but, as a colony, we have not now "all our eggs in one basket," and from tea especially we may expect great results. It is well this should be known at a time when the fall of the Oriental Bank and the Ceylon (far more properly the Mauritius) Company (Limited) is likely to do so much harm to the name and repute of Ceylon. It should be widely known that we have in a healthy climate, in splendid roads an admirable railway system, in cheap free labour, every co-

* Up to the time of the Dutch, in fact, little was made of coconut cultivation in Ceylon, and the first cargo of cocoanut oil from Ceylon came to Europe in 1820.

† Mr. Mosse quotes Mr. Twynam's report on the benefit of irrigation for fruit-culture in the Vanni district.

couragement for Tropical Agriculture in Ceylon. Our natives are being so rapidly educated that by 1,900 A. D. English will practically be the language of the larger body of the people. Colombo is the centre of the Eastern world, thanks to Sir John Coode's new harbour; and capital invested in tea and cacao culture especially, is as likely to bring a good return as any agricultural enterprize I know of anywhere.

Mr. A. N. BIRCH, C.M.G.: I am very glad that an evening has been given by this institute for a discussion on the interesting subject brought before the meeting by Mr. Mosse in the paper he has read. It is a subject that may not greatly interest the majority of those who usually attend these meetings, but it is a very important one, which has little chance of publicity. The merchants and planters have a very active press in which to ventilate their wants and grievances, but the natives of the interior have hitherto depended solely on the Governor and public officer to help them in their distress. I had the good fortune to hold office in Ceylon at a time when the island was very prosperous. There was plenty of money for public works, and we had an energetic and very able Governor in Sir William Gregory, to push forward irrigation works. I have visited more than once, all the districts referred to by Sir William Gregory, and I can thoroughly endorse all he has said of the terrible sufferings and distress existing in the interior of the Island, and the marked results of the irrigation works where completed. It has been a matter of great regret to me that since I left the colony there has been a great annual reduction in the irrigation votes, and consequent stoppage of many important schemes commenced in my time. The great reduction in the revenue has been the main cause of this, no doubt. But I trust and believe that the new Governor has the interests of the natives thoroughly at heart, and will spend every penny he can in pushing forward this great work of restoration. I was chairman of the committee from whose report Mr. Mosse has quoted, and although seven years have passed since that report was written, I am as strongly convinced as ever that the great object for the Government to accomplish is to make the country produce enough grain for its native and immigrant population, and to accomplish this it is desirable to continue, on a larger scale than hitherto, the restoration and improvement of irrigation works throughout the country." I cannot, therefore agree in much that Mr. Ferguson has said on the question of rice cultivation. Past history shows that Ceylon was a large grain-producing island, as I trust it will be in the future, when the restoration of the old tanks is completed. If this meeting has the result of calling public attention to the matter it will have done good.

Mr. Charles BRUCE, C. M. G.: Although my official connection with Ceylon ceased some time ago, my interest in the colony has not ceased, and I consider it a privilege to be present tonight, and to be allowed to take a part in these proceedings. And, indeed, as Mr. Mosse has remarked, the subject is not one of interest exclusively to Ceylon. It has an interest for other colonies; and in Mauritius, with which colony I am now officially connected, there is no question which is attracting more serious attention than the storage and distribution of water both for drinking and for agricultural purposes. With, regard to the subjects directly dealt with in Mr. Mosse's paper, I will confine myself to just two points. Mr. Mosse has called attention to the system of Rajacaria, and with what he has said on this subject, as well as with the remarks of Sir John Douglas on the same topic, I generally concur. There can be no doubt that at the time Rajacaria was abolished by order in Council, Englishmen in England knew more of the later abuses of the system than of its legitimate uses. The translation of the term may perhaps have led to some confusion. If the term is translated "forced labour," as, I think. Mr. Mosse has called it tonight, it is difficult to dissociate it from the odious significance which is attached in France to the expression *travaux forcés*, but if we use the sufficiently literal translation, "On the king's service" or "On Her Majesty's service," we have an expression which has rather an honourable than an odious importance, and which perfectly conveys the impression of the thing signified. Rajacaria was originally work done for the public advantage and for public uses, but in course of time the term got to be almost exclusively associated with the idea of work tyrannically imposed upon the people either for the exaltation of the sovereign in the construction of public monuments for purely selfish purposes having no other object than the personal gratification of princes or administrators. In the irrigation works recently undertaken in the North Central Province of Ceylon, a system somewhat similar to Rajacaria has been, as Mr. Mosse has explained, resorted to, and I think that all who are present and who are acquainted with the financial possibilities of Ceylon, will agree that without some such system it will be impossible to carry out the beneficial schemes which have been explained to us here to night. Such a system, however, must be limited by two conditions: it must be resorted to only for the construction of public works of recognized and obvious utility; and it must be worked through the agency and with the consent of the local native authorities, so that the persons called upon to contribute their share of labour or its equivalent may be thoroughly satisfied that they will not be called upon to perform any work for the personal advantage of any English administrator or official, but will be asked to co-operate only in the carrying out of works demanded by their own general needs and for the general advantage of themselves and their posterity. (Applause.) Mr. Mosse has in his paper given us a narrative of irrigation in Ceylon, and has recalled the names of kings and princes famous in the history of the honourable works connected with it. I think that in modern times no one has more fully recognized the importance of the subject or deserves larger credit than Sir William Gregory, who has addressed us this evening. (Applause.) I am sure also that we have all heard with pleasure what he has told us about the works now being undertaken by Sir Arthur Gordon. But in the history of irrigation in Ceylon there is a class of men to whom, in my opinion, great credit is due, and who have not, I think, been mentioned. I allude to the the officers and men of the Public Works Department. (Applause.) In the course of my official duties in Ceylon, as Director of Public Instruction, I visited nearly every part of the island, including those districts where fever and sickness are almost constantly prevalent. Everywhere I found the officers of the Public Works Department (and I speak especially of those connected with the Irrigation Department), at their post, Sir John Douglas, Mr. Birch, and others present, will, I am sure, concur with me in bearing testimony to the patient, the devoted, and efficient but often scarcely recognized labours of these valuable public servants. It gives me pleasure to take the opportunity now offered me of calling attention to the gallant endurance with which, in remote and obscure districts, constantly attacked by fever both in their own persons and in their families, they devote themselves to the service of Government and to the interest of the people entrusted to their care. (Applause.) And now let me say that I came here tonight, not to speak, but to learn, and I have learnt much, not only from Mr. Mosse but from others, and especially from Mr. John Ferguson. I think we were very fortunate in having had him here this evening, for on all subjects connected with Ceylon he can speak with authority. Indeed with the exception of Mr. A. M. Ferguson, the senior Editor of the Ceylon *Observer*, there is probably no European who has so intimate a knowledge of the affairs of Ceylon generally as he has. (Applause.)

The CHAIRMAN: It is now my agreeable duty to ask you to convey to Mr. Mosse your best thanks for his interesting and instructive paper.

Mr. MOSSE, in reply, said: I thank you very sincerely for your approval of my paper. The subject is, of course, a large one, and there are various points of view from which it may be regarded. It is, however, quite clear that since irrigation has been adopted crops, before uncertain have been rendered certain, that prices have been materially reduced, and that there is plenty of food in place of scarcity. I will not, at this late hour, enter into any discussion as to forced labour, or labour "on Her Majesty's service," and statute labour, but I think everybody ought to be very thankful for the beneficial results which have attended the present system. (Applause.)

The Chairman announced that the next meeting of the Institute will be held on Tuesday, June 10, when a paper will be read by Governor Sir Frederick A. Weld K. C.

M. G., on "The Straits Settlements and British Malaya." (The Right Hon. W. E. Forster, M. P., will preside.) Also that the Annual Conversazione will be held at the South Kensington Museum on Thursday June 19th.

The meeting then separated.

COCONUT CULTIVATION.

(*Continued from page 3.*)

Gratitude of the Coconut for Fertilizing Matter.—On all soils, except the most fertile, the presence of a human habitation in a coconut field can always be distinguished at a distance by the superior height and luxuriance of the trees that surround it. The native accounts for this appearance by saying that the coconut loves the sound of the human voice. This is on a par with the old theory of the water rising in the pump, because nature abhorred a vacuum, which held its ground till it was discovered that nature's abhorrence of a vacuum was only thirty-two feet deep. The bulk of the Sinhalese people have not yet discovered that whistling gigs to a millstone would be quite as useful as singing the gems of vocal music to a coconut tree. The true cause of the better thriving of the trees round a dwelling is natural manuring. Where a family and their usual stock of domestic animals reside, there are daily droppings of fertilizing matter within the circle they frequent, decreasing from the centre outwards. The trees nearest the house are always in bearing years before the out field, and they always continue the most productive throughout, or as long as the house remains inhabited. Put a set of lines in the most backward part of a field, and improvement begins at once. This proves the gratitude of the coconut for any help, however small, that either by accident or design is given to it, and suggests hastening the profitable period by artificial means. On most places, a few trees near the house, flower in the sixth year, some even in the fifth, and yield a fair crop in the eighth, whereas those that have had no manure do not begin before the tenth year and struggle into bearing, one by one, up to the twentieth, while the best that the natural soil can do is not attained before the twenty-fifth. There is not within my experience any other plant that so quickly and fully responds to fertilizers and much or little the result is proportionate. If one tree favourably situated can bear a crop in the seventh year, a whole field may be made to do the same, the question being: "Will it pay?" To answer this question the cost of opening a coconut field must be analyzed.

Native Practices: Calculations of Cost.—By goyas, the field will be cleared without money spent; and in a very favourable case, the land-share of the secondary crops, will cover the cost of lining, holing and planting, and the owner takes over his field free of all costs, to him, except the fee simple of the land, and the accumulated interest on it. The field is then left to grow up in jungle for three years, when there is the alternative of clearing the jungle or letting it grow on, and finally smother 90 per cent of the plants, whereas the reclearing of the jungle, if done in the sixth year, will probably save 50 per cent. The field may then be left till the most forward trees begin to flower, say in the twelfth or thirteenth year, when the final clearing takes place; and in favourable cases 40 per cent of the trees will be alive, and 10 per of these in bearing, the remainder being of all sizes downwards, in the event of steady cultivation being then carried out, in keeping down the jungle and replanting the vacancies. The annual expense per acre will be R12, and only about the twentieth year, will the field be yielding enough to cover its annual cost, while 10 per cent of vacancies will still exist. Thus the absolute cost in money of bringing coconuts into bearing, in the most slovenly and desultory manner, will be R120, R30 of which will be recouped by produce up to the twentieth year.

Effects of Lantana.—I have assumed that the land dealt with is of average quality, and that the indigenous jungle alone has to be treated; but if lantana obtains a settlement in the third year, and is left untouched for the next three, not one coconut plant will survive till the seventh year. When lantana gets into a clearing, it thoroughly masters and keeps down every other growth that it overshades, but any tree that has got above its usual range of seven or eight feet is safe from being smothered. However, its growth may be retarded by the struggle to obtain food in the soil against such an active and greedy foe. The presence of lantana in a clearing guarantees the extermination of every other member of the vegetable kingdom that depends on the first eight feet in space for its air, light and sunshine.* It has rather bothered the old school coconut planters.

Calculations of Proceeds.—The chances are that under the above system the yield of average soil will be 1,000 per acre, worth (say) R30. There is R90 to make good, the interest on which, at 10 per cent, is R9; the current expenditure is R12, and there is R9 over to be deducted, if we value the proceeds at R30. Supposing the annual increase of proceeds, to be R5, it will take five years to rub out the R90 that stood at debit in the twentieth year. Thus in the twenty-fifth year, the place is clear, and the annual average income per acre will be thencefourth R38 per acre, so long as the price keeps up to R30 per 1,000, and this calculation drops all the back interest on the original cost as well as on current expenditure; from the twelfth to the twentieth year, which, if taken into account, would leave from R60 to R70 to be made up before the property was thoroughly clear of debt. This is by no means a fancy sketch, but almost the exact history of more than one property that I have had under my own observation during the whole course of their existence.

Another Sketch.—I will now give another sketch of what happened on the adjoining lot to one of the properties described above. The land was felled, cleared and planted, but the jungle got up again so rapidly, that, at the end of twelve months, it was ten feet high, and the wild pigs have done "their worst" with the plants—only four plants remained in the whole field. This was rather discouraging, but the proprietor had a good deal of latent pluck, and the second year went to work on a new plan. The jungle was regularly rooted out, at a cost of R20 per acre, and planted with cassava, to which the pigs more earnestly inclined than to the coconut plants, and thus about 70 per cent were got out of this danger. The vacancies were regularly supplied twcie a year, but at the end of nine years they still amounted to 10 per cent. In the meantime continual war was made against jungle and lantana, and when the trees were four years old, the pasture grass was mid-leg deep. Cattle were then introduced, but, as many of the plants were not out of danger, they were tethered out of reach and shifted as required. Before the end of the fifth year 10 per cent of the plants were in flower, and three-fourths of all that had been treated with cattle-manure, were in bearing before the ninth. Further deponent sayeth not, as the ninth year is not yet ended. The trees that began to flower three years ago have now crops of from 50 to 150 nuts; allowing for all accidents, they will average 80 per tree, or 5,600 per acre, which at R30 gross proceeds R180. I think the proprietor would have refused me his permission to tell in Negombo and publish in the streets of Colombo that he had expended above R200 per acre on coconuts before obtaining any appreciable return. It would have blasted his character as a prudent and intelligent person for ever, unless accompanied by the further fact that every penny principal and interest would be returned before the twelfth year leaving a very valuable property in his hands. The only thing that has been brought into this property by way of manure was one-third of a ton of quicklime, at a cost of R7·50 per acre. As everything done on this property was experimental, the expense would be very considerably reduced by the knowledge acquired of what to do, and how and when to do it. It may be added that the land in question is very much above an average quality, which, if favourable to results, greatly enhanced the cost. There is a portion of this property that has never got any cattle, manure but in every other respect the treatment has been the same, and there is no outward difference in the soil; yet there is a marked difference in the trees, not one of them being in bearing and many not even so advanced as to show stem. As their wants cannot be supplied from internal resources, the proprietor states that he will give each of them 12 cents worth

* "The survival of the fittest."—ED.

of poonac at once and repeat the dose yearly till uniformity is attained.

How an Old Estate was Treated and How it Responded.—Having thus told what has been done in hastening the maturity of young coconuts in good soil by manure made on the spot from the natural produce of the very land on which the plants stand, I proceed to relate what was done with trees twenty-one years old on very poor sands. The estate in question at twenty-one years old yielded a crop averaging 13½ nuts per tree, and that was the largest it had ever given. The copperah was worked up on the place; there was a large stock of half-starved cattle, and a stock of pigs were kept; but all this had got the crops no further than 13½ nuts per tree. At this stage, a new manager took charge, and, after due study of the situation, he submitted a scheme that added about 10 per cent to the average annual expenditure. Some of the points were strongly opposed by the agent, but, being a reasonable man, he finally gave in to the reasons adduced and sanctioned the complete plan. The pigs were got rid of, as their local value was then only about 25c a stone dead weight; one-third of the cattle stock was sold off by auction without reserve; the whole remaining stock were allowed the liberty of the poonac tubs, and a shed was constructed roomy enough to hold the whole comfortably. There were extensive deniyas on the property overgrown with pan-ferns and course grass, and four boys were set with small single bullock-carts to cut and bring this stuff to the cattle shed, and spread it over all. Thus in the course of six months, there was a depth of from two to three feet of excellent manure. At the opening of the monsoon rains, the cattle were moved to a fresh shed, and the manure carted out and laid down at the rate of two and a half cubic feet to each tree; it was then scattered equally over the surface and dug in with mamoties. The improvement of the trees and the increase of crops that followed this treatment was marvellous. All the manure that could be made on the estate, however, was a mere drop in the bucket; such a manuring only total on three crops, while it would have taken, 12 years to go over the estate. Still even this was sufficient to cause a steady annual increase of crops from 13½ up to 21 in six years. After some trouble, permission was granted to try steamed bones, and in the sixth year, one tons was used with such satisfactory results, that two tons per annum were allowed for the next four years, with the result of 33½ nuts per tree in the eleventh year. Shortly afterwards this estate was sold to natives, and six years later the crops were said to have fallen off to 12 nuts per tree. The whole cost of manuring during those ten years aggregated R1 per tree, and the value of something over R3 thus recovered giving a return of 300 per cent on the outlay in four years, and there is not the least doubt that five times the amount expended within the same time would have given equally satisfactory results.

The Coconut Tree, a Chemical Apparatus.—I look on a coconut tree as a chemical apparatus, for turning carbon, oxygen and hydrogen into oil. Those elements are not counted in estimating the fertility of soils; indeed it is probable that plants derive these whole supply from air and water. If this is admitted, it follows that no quantity of oil removed from a given area of land in any way tends to impoverish the soil. But the coconut tree cannot make oil without a proportion of other elements that it combines; the process requires nitrates, phosphates and alkalies, to complete the operation, and these it must obtain from the soil. Extract the oil and return all the other products of the tree to the soil it occupies, and there will be no diminution of the average yield of oil, as long as the tree lives in health. Increase the supply of nitrates, phosphates and alkalies in the soil, and in due proportion the tree will produce more oil, while the fertilizers introduced are a permanent gain.

Replacing Fertility Removed: Poonac as Manure.—The coconut planter, who desires to maintain the average crops of his property, will do well to ascertain the average of the fertilizing elements removed in a given number of nuts, and set aside such proportion of the price as will replace them. The sure way is to manufacture his oil on the spot and retain the poonac; but sometimes it appears more profitable to sell the nuts as they stand than to extract the oil and sell it seperately, because the cost of manufacture, with the primitive apparatus he must employ, is greater than with proper machinery; but if he knows exactly how much nitrate, phosphate and alkalies are in a candy of copperah, and their prices, he will know how to proceed in his purchase of fertilizers so as to maintain or improve the condition of his land. There may be better forms of fertilizer than poonac, but 140 lb. of poonac will as a rule restore all that is carried away in 1,000 nuts, and, when this quantity can be obtained for R1·25, there is no cheaper way of giving back what is taken away; besides it has an advantage over every other form of manure in supplying all the elements of the coconut in the exact proportions required, while the loss, by putting it through the alimentary apparatus of a cow, is very small.

Manure Made from the Coconut Field: Manuring Begin Early.—Manure made by cattle fed on the grass of the coconut field adds nothing, to the general fertility of the land; it merely removes it from one place to another; but while the plant is young, and only commands with its roots a small proportion of the space assigned to it, the placing of it within reach of the roots in this form is of high importance to its rapid growth and early bearing. It is not the amount of food thus placed within its reach that limits the good done, the roots are stimulated to push out further into the soil, and thus acquire a wider feeding-ground. Small doses frequently repeated are far more beneficial than greater quantities at long intervals; and in every case, it should be buried under at least two inches of soil. I would recommend, in putting out the plants, to dust a couple handfuls of quicklime into and round the hole, and I would give each at the same time 1 lb. of poonac. A good start is half the battle, and what is once gained should never be lost for want of a little stimulant. I cannot expect the tree to yield me an annual revenue of from two to three rupees, unless I use every means in my power to establish its constitution; and in the whole range of vegetation, I believe, there is no plant that will do so much for itself with so little help. I would spend 50 cents per tree, in building it up during the first seven years, after which time, it will give a return, within four years, of three nuts for every 5 cents worth of manure given. There is no practical limit to the yield: I have known one tree that for a series of years bore 400 nuts; I saw another a few days ago that was very little behind it, and I have known many individual trees that regularly yielded from 200 to 300. In such cases, there is no doubt much in the individuality of the tree, and special suitability of the soil; but my contention is that any tree that bears a small crop in any soil may be made to bear a large one, the only difference being that a good soil gives a good crop without assistance while a poor one gives a poor return, but the one will respond to manure as readily as the other. The same amount of manure will result in the same addition to the crops, whether the trees to which it is administered have previously been bearing ten nuts or fifty per annum. The weaker tree may appropriate some part of the manure to build up its strength, and, if the soil it occupies be deficient in the capacity of retaining moisture, it may be unable to appropriate at once the food within its reach, but the manure once in the soil will tell sooner or later.

Register of Treatment by the Coconut Stem: Treatment of a Single Tree and Result.—The stem of a coconut tree on poor land forms a complete register of the periods at which manure has been administered, the effects it produced and the time during which it operated and became exhausted. It contracts under the pressure of want, expands when fed liberally, and again contracts when all the food is used up. There was a tree that had stood for twenty five years on sand so poor, that not a blade of vegetation was ever seen within twenty feet of it; the stem, over one foot in diameter at the surface, gradually diminished upwards, till, at the five feet of height attained, it was less less than four inches and the length of the leaves were about thirty inches. In very truth, no more wretched specimen of a still living plant could have been conceived by the mind of man, and it was only for the sake of proving the theory that its treatment was undertaken. Twenty pounds of poonac and five pounds of steamed bones were mixed and sown broadcast in a circle twelve feet in diameter,

and dug in. It began to grow vigorously at once, and each fresh leaf that expanded was an increase on the length of its immediate predecessor till at the end of twelve months they reached fifteen feet; at eighteen months it produced its first flower and was again manured with five pounds of poonac and two pounds of bones; at thirty months it began to give crop, and the top was so heavy that there appeared some danger of the small part of the stem giving way, but this did not happen, and, for the three succeeding years, the same dose of poonac and bones were given. At the end of the fifth year, it was a handsome, vigorous tree with the stem immediately under the leaves over one foot in diameter with a crop of from 60 to 70 nuts, while the aggregate of previous gatherings was over one hundred nuts. I have only to add that the cost of these results was 75 cents.

Confidence of Some Ignorant People and Assertion of Scientific Truth.—I felt much hesitation before deciding to tell this story as there are hundreds of men in Ceylon, who consider themselves no mean authorities on coconut culture who will without further ado pronounce it an absurd impossibility. There are truths that science has made common property, but which few coconut planters have yet asserted their right in, or indeed become aware of their existence. How few of them know that 187 lb. of poonac, contains all the elements, that is removed from the soil in a candy of copperah (560 lb.)? How few of them know, that the poorest soil may contain some of the elements of fertility that the plant cannot assimilate from the absence or deficiency of other necessary elements? How few of them know that a very slight dressing of the deficient elements will produce immediate and abundant effect. A few measures of quicklime, may bring into activity a great fund of latent fertility; a few ounces of bone-dust may be the one thing wanted in the soil to put a good crop on a barren tree.

Goyas and Agricultural Science.—Were the principles of agricultural chemistry explained to a Sinhalee goya, he would pronounce it a mythe and his informant a humbug; but ascribe any special success to having entered into communication with a beneficent demon who for certain considerations came every night to bless the trees, he would firmly believe the statement, and from thenceforth would display an increased respect for the recipient of supernatural favour. As such men have really been the practical creators of the coconut industry in Ceylon, and really know more of the matter than those who purchased the land, there is nothing surprising in the fact that scientific treatment has not progressed with the breadth of cultivation, and not much can be expected in this direction till the agricultural school begins to turn its graduates loose on society. There are not half-a-score of Europeans that know anything of, and hardly one-half of that number who retain a practical hold on coconuts. There are no doubt many educated and intelligent proprietors, but very few of these are practical planters, and not one that I have come across will deign to look on the scientific aspect of the culture. I have often heard it laid down as an incontrovertible rule that no coconut should be manured before it came into bearing. I invariably found that the parties asserting it had never tried it. A few weeks ago a party who was not a planter warned me against the practice. I told him that he ought to have dismissed that prejudice with his kondeand his comboy, for it was utterly at variance with a short crop and a pair of tweed trousers.

FOR HARDENING BUTTER.—For hardening or rendering butter firm in warm weather use carbonate of soda and alum, made into a powder. For twenty pounds of butter, one teaspoonful of powdered alum and one of carbonate of soda are mingled together at the time of churning and put into the cream. The effect of this powder is to make the butter come firm and solid and to give it a sweet flavor. It does not enter into the butter, but its action is upon the cream, and it passes off with the buttermilk. The ingredients of the powder should not be mingled together until required to be used or until the cream is in the churn ready for churning.—*San Francisco Chronicle.*

ANTS.—Chloride of lime has been found effectual in driving away ants. A small quantity will suffice. It may be dusted about their runs, or rubbed into cracks in the walls or elsewhere from which they emerge.—*Leader.*

IMITATION GROUND GLASS can be prepared by dissolving two tablespoonfuls of epsom salts in a pint of lager beer and painting the glass with the mixture. After drying, the glass will appear as if frosted.—*American Cultivator.*

MICA.—The principal utilization of mica is for stove and furnace doors. A small amount of specially fine mica is used for compass plates. None but clear, transparent sheets or plates of mica can be used for such purposes. The inferior quality is used as an absorbent in one variety of nitro-glycerine explosives and in a lubricating composition for axle greese. Ground mica is also employed for ornamental purposes. The value ranges from twenty-five cents to five dollars per pound, according to the size of sheets and quality. North Carolina has furnished the most valuable quality.—*Industrial South.*

USES OF TEA.—Save the tea leaves for a few days, then steep them in a tin pail or pan for half an hour; strain through a sieve and use the tea for all varnished paints. It requires very little elbow polish, as the tea acts as a strong detergent, cleansing the paint from all impurities, and making it equal to new. It cleans windows, and sashes, and oil cloths—indeed, any varnished surface is improved by its application. It washes window-panes and mirrors much better than water, and is excellent for cleaning black walnut and looking-glass frames. It will not do to wash unvarnished paints with it.—*Rural Californian.*

THE RUBBER INDUSTRY OF THE UNITED STATES has no rival in foregin countries. There is something like $75,000,000 invested in the business of manufacturing rubber goods, $30,000,000 of which is confined to the rubber boot and shoe industry. The total number of employees is placed at 15,000, and the total number of factories at one hundred and twenty. According to a recent census bulletin the value of the annual product is $250,000,000. Some 30,000 tons of raw rubber are imported every year, which, when combined with other materials in manufacturing, amount to 300,000 tons. The market price of the raw material has been forced up to $1·25 per pound, while six years ago the price was scarcely fifty cents. In consequence of the advance in price, several substances have been prepared as substitutes for it, of which celluloid is the most important. —*Industrial South.*

BONE DUST AND WOOD ASHES.—A farmer in Indiana gives the following result of an experiment with bone dust and wood ashes. He says:—"I applied six hundred pounds of dry, unleached ashes to the acre, and sowed wheat on that, and the result was only six bushels to the acre. Adjoining this tract I drilled in two hundred pounds of bone dust and the three acres produced twenty bushels to the acre, being an increased yield of fourteen bushels over the tract sown with wood ashes. The following year I used five hundred pounds bone dust on the plat where I had previously sown six hundred pounds of ashes, and the result was forty bushels of wheat to the acre, being double what the bone produced alone. This experiment satisfied me that ashes alone or bone dust alone would not give me a yield that paid to my satisfaction."—*Southern Planter.*

IN the French journal, *La Ramie*, M. Pailleux calls attention to a Japanese plant named *Kusu* (*Pueraria Thunbergeana*), the roots of which contain starch, while the leaves and shoots are used as food. Its fibrous portions are adapted for use in the manufacture of cordage. It is a lofty and hardy plant, attaining within a year a height of from 12 to 25 feet. It yields fruit, and grows upon the most unfruitful dry ground where nothing else would thrive, provided there is a sufficiency of warmth. It requires no care, and can be propagated by seeds or by planting. A plant named *Kappe* was shown at last year's Amsterdam Exhibition. It is indigenous to Java, and when its fibres are carefully prepared they resemble wool, and when curled, at a moderate cost, can be used for stuffing mattresses. It can also be spun and dyed, but the fibrous appearance it retains shows that a radical improvement in the method of treating it has still to be discovered. All who examined the fibre at Amsterdam were satisfied of its contingent importance as a textile material.—*Indian Agriculturist.*

SUGG'S STEAM COFFEE-ROASTER.

A few weeks ago Mr. Walter King, Bolt-Court Loudon, published a pamphlet that deserves the attention of all who are fond of a cup of *good* coffee. It is entitled: "Coffee and the application of Gas to Coffee-Roasting, by William T. Sugg."

It would appear that in England as well as Holland, the proper preparation of Coffee is an unknown art, and, as the author says, it has become an article of faith that the English have no coffee that is worthy to be called by that name. This is a great error. The very best raw coffee can easily be obtained, but it is generally spoiled by the manner of treatment.

The only great secret in the preparation of coffee is that it *must* be freshly roasted, and ground, if possible, while hot. At all events, it ought not to be kept longer that a few days, if we wish to taste the true flavour of the coffee. The aroma is very volatile and soon passes off.

Hence coffee, even if pure, roasted in large quantities and kept at the grocer's till purchased, loses all its aroma, and the ordinary process of roasting it in a cylinder turned by a handle over a charcoal fire, is too tedious for household use; therefore the author of this brochure, who has tried coffee-roasting in small quantities in a variety of ways, has considered it in all its bearings.

After many trials he has succeeded in designing a new coffee-roasting apparatus, which is entirely self-acting, speedy and practicable.

This apparatus shown in the diagram given below, consists of a close-ended cylinder with a sliding door in it, into which the coffee berries are put. The cylinder is provided with a central shaft running through it, and projecting out of it at each end. One end is fixed into a wooden handle, and at the other is the bearing on which it turns. Close to the handle is a cogwheel which, when the cylinder is put into its place ready for roasting, gears into an endless worm. The worm is driven by a small *Steam-Engine*, working under a pressure of 1 or 2 lb. to the square inch.

The steam for working the little engine is produced from a small brass boiler, strong enough to withstand a pressure of 150 lb. on the square inch. The working pressure is not more than 2 lb., so that it is perfectly safe in the hands of the most inexperienced, the more so, as it is provided with the necessary safety apparatus. A pipe from the boiler communicates with the condensing box at the back of the apparatus, into which the steam from the engine condenses. The engine-boiler is heated by a small gas-burner under it.

The coffee being placed in the cylinder, and the engine set going, a series of burners under the cylinder roasts the coffee. This gas is also regulated, so that it can always be turned on full and left to work by itself when the coffee is roasting.

The speed of the coffee-cylinder is 10 or 12 revolutions per minute, a little faster, or a little slower, will not hurt. When properly regulated it will take from 12 to 15 minutes to roast the coffee. The quantity of gas required for a charge of ¼ lb. is from 2½ ft. to 3 ft. the cost of which is less than half a farthing.

After the apparatus is started, it may be left alone to work by itself for about ten minutes, or until the scent of the roasting coffee proclaims that the work is approaching a satisfactory conclusion. The aroma of the coffee is exceedingly pleasant, and it is one of the best deodorizers we have.

A trial or two will be sufficient for the acquisition of the necessary skill for the successful use of the apparatus.

So much for the machine. The writer then goes on to explain the best methods for making *good* coffee, which would lead us too far from our object, which is to make our readers acquainted with this useful coffee-roaster.—*Indian Mercury.*

GROUND PEPPER.

The attention of the trade is being seriously directed to the fact that so-called ground black pepper is being freely offered at prices far below the cost of the lowest whole pepper, which is the more remarkable, as the cost of, and loss in, grinding is at least ½d. pound. The chief explanation of this remarkable state of things is to be found in the following facts:— White and black peppers are both, as is well known, the produce of the same vines, and the difference is simply due to the removal of the outer or darker portion of the corns in the former: white pepper being the same as black but less the dark skin. This envelope, or outer coating, used always to be removed abroad, and by a process which, if it be as is reported, was by no means an agreeable one to reflect upon. Some years back, owing to speculation, white pepper was driven up to famine prices. It was then found that black pepper could be husked here by suitable machinery, and that the resultant white pepper had a preferable colour, when ground, to that which was made abroad. Consequently the process known as "decorticating," that is, of removing the outer husk from black pepper, and of leaving only the central white portion of the corns, has become general here. The question then arose of what was to be done with the large proportion of black husks which were removed by decortication, and it has been solved by simply grinding them up with whole black pepper, and selling the produce as ground black pepper. The white pepper prepared in England by decortication fetches such a high price, that the refuse husks can be sold at an exceedingly low rate, and then mixed off, and used to reduce the selling price of ground black pepper far below the original cost of the raw material.

The question whether such a practice is allowable is one of degree, for black pepper has always been ground with its husk, but the mixture, in the process of grinding, of a larger proportion of husk than appertains to the pepper, might be carried on to a point, at which the product might be more rightly termed ground black pepper husks. Still, the practice could scarcely be called adulteration, as the husk has pungent qualities, serviceable for the uses to which pepper is put, and it is not proved that the inside of the grain is more useful than the outside. Indeed, a large number of persons much prefer black to white pepper.

It is also to be said in favour of the husks in question, that decortication cannot be well practised with the very lowest qualities of black pepper, so that the husks are from a superior quality of pepper to that which is often ground. Still, allowing all this, there is much to be said on the other side. A wheat miller may with perfect propriety sift his flour into various degrees of whiteness, and offer it as first, seconds, and thirds, mixing off a portion of the bran, but if he ground up his bran by some new process so as to make it resemble flour, for which he passed it off, he would be doing something more nearly resembling what has recently been done with pepper. The spice grinder, in the same way, may sort out his pepper into various degrees of fineness or colour, and offer them at proportionate prices. But if he exaggerated the operation, the question would certainly arise whether he would be justified in grinding the husks, and then, by implication, selling them as the produce of the entire peppercorn—for such ground black pepper is certainly supposed to be.

It is well to remember, if any public question arises as to these matters, that the whole consequences would fall, not upon the wholesale dealer, but upon the retail grocers. If the latter offer as pepper, that is, as the produce of the entire corn, a material containing, say, 50 to 80 per cent of the husks or shells, the fact is sure to be detected by the chemical tests now in vogue, especially as the proportion of dirt always contained in unscreened pepper, even of the fine pepper used for decorticating, is to be found entirely in the husks. The law would find out the misrepresentation by discovering the differing proportions in the constituents of ground pepper and ground husks, and not improbably arrive at the conclusion that there was none. It is true that it is not believed that any one has as yet gone so far as to grind husks only and call them pepper, but, judging from the prices quoted, a good deal of progress has been made in that direction. Of course, pepper ground whole, as has been said above, must include some husks, and therefore all these points are questions of degree. The grocers, however, run a serious risk in buying very low-priced ground peppers, and considering the small importance of the trivial extra profit, even to those in a large way of business, it is surely to their interest to discourage to the utmost all such departures from an old-established practice. Already not only are husks very freely employed to "reduce" cost, but long pepper, a totally different commodity, is added to the

product, to "improve" colour. In fact, owing to the demand caused by its being mixed in this way, long pepper has recently risen about 9s. per cwt. If the grocers wish to avoid another question between them and the analysis, like that of coffee and chicory, or that of mustard and sago flour or other ingredients, they should decline to buy any pepper but that ground from the whole corns for the gain of the substitution of the one for the other would not be worth considering to any individual retailer.

[The above is taken from the *Southern Planter*, but is not complete, the copy of that periodical which reached us having been defective.—ED. *T. A.*]

SCIENCE IN AGRICULTURE.

BY SIR J. B. LAWES, BART., LL.D., F.R.S.

In the February number of the *Southern Planter* I observe some very sensible remarks of Professor Scott, to the effect that science places at the disposal of the farmer the principles upon which his acts are founded, but that his own intelligence and experience must instruct him as to their application; and he further adds that "every farm is to a certain extent a separate problem."

About a quarter of a century ago I published a table giving the relative manure value of a great many of the cattle foods used upon the farm. The construction of the table was very simple. I took the best analyses of the foods which were to be obtained at the time, and deducted from the nitrogen, phosphoric acid, and potash the amount of those constituents which—from my own experiments on feeding—I considered would be assimilated by the animals consuming the foods. I then placed a value on the residue somewhat below the cost for which a manufacturer would furnish a manure in every respect equal in value.

I have no doubt that the table could be made more perfect at the present time, but with all the increased knowledge which we have acquired in regard to the action of manures, there is nothing to alter in the principle upon which the table was constructed. Decorticated cotton cake would still head the list as furnishing a manure superior to any food used in Great Britain. There are other foods which have a comparatively low manure value; and I noticed in a trade circular not long ago, one rather high priced food which would be almost without any manure value at all. The cost of a food therefore bears no fixed relation to its manure value.

At the commencement of the present year an act of Parliament came in force securing to the tenant farmer of Great Britain compensation for the manures applied by them which remained unexhausted at the time of their leaving their farms.

The act further gives the landlords and tenants the power to form some scale of compensation among themselves: that is to say, the land owner and the tenant may come to an agreement between themselves as to the sum which shall be paid the latter on his leaving his farm, as compensation for the cattle food consumed. Both sides in fact contract themselves out of the act; but with this proviso, that the compensation must be fair and reasonable: in other words, the land owner should not put pressure upon his tenant to compel him to sign away his rights.

It might be thought that, with some slight revisions and modifications, such a table as that which I had constructed would form the basis of cattle food compensation. Such, however, is not the case, and the popular idea is that some portion of the cost of the food should be the basis of the manure value.

As this view has been advocated by intelligent farmers who are thoroughly conversant with the contents of the table, I think it will be admitted that the progress of science in agriculture is somewhat slow in this country.

Your correspondent refers to my having said that sodium supplies the place of potassium when the latter is deficient in the soil. I do not now recollect the exact expression I used when writing on the subject, but I certainly did not wish it to be understood that sodium could perform all the functions of potash.

We are just now sending a paper to the Royal Society on the composition of wheat grain and straw; but notwithstanding that in some of our experiments soda has been used without potash, and in others potash without soda, for twenty years in succession, soda is hardly to be found in either the grain or the straw.

When, however, we come to write upon the composition of the ash of pasture grasses, we shall show that while the grass—when supplied with a sufficient amount of both potash and soda—will always select the former; if it is supplied with the soda alone, it will take up such a large amount of that substance that more soda than potash is found in the ash.

These facts may be thoroughly relied upon, as they are based upon the most exhaustive and complete series of ash analysis which have ever been carried out.

Mangles supplied with soda will take up large amounts of that substance; while potatoes under similar circumstances do not take up any. The juice of potatoes—where we should expect to find any soluble salts taken up by the plant—contain hardly any soda, even when manured with nitrate of soda. The juice of mangles, on the other hand, under similar circumstances of manuring, contain almost as much soda as potash.

It is these special properties of different classes of plants that make our attempts to give any exact explanation of the economy derived from a rotation of crops so exceedingly difficult.

There is another peculiar property of plants which requires to be thoroughly studied. I allude to the different capacity possessed by different plants for taking food out of a soil. Without at all arguing that red clover derives its nitrogen from nitric acid, I have pointed out that it has greater advantages than any of the other agricultural plants commonly grown for taking up a substance which is diffused so rapidly through the soil. It has a longer life, and the plant grows very close together on the soil; the roots penetrate deep into the subsoil, and the leaves are always green. If, however, red clover can obtain more nitrogen from the possession of these properties, it might be supposed that they would have enabled it also to collect more mineral food. I should certainly have imagined that such would have been the case.

Let us see, however, what experiment tells us. At Rothamsted, between 1850 and 1873, wheat, turnips, barley, and beans were grown upon an unmanured soil. In 1874, red clover was sown and the plant was very good, although the crop was small. Between 1873, when the seed was sown, and June, 1874, when the crop was cut, all the phosphoric acid which it could pick up out of an acre of land only amounted to 2½ lb.! It may be said that after the removal of so large an amount of crops the soil was exhausted of its phosphoric acid, but such was not the case, as the wheat which followed the clover took out more than 17 lb. of that substance; while the turnips which followed the wheat fared even worse than the clover, for they could only obtain 1½ lb.; but the barley which followed the turnips took out 10 lb., and in 1883—after 36 unmanured crops had been carried off—the wheat removed 20 lb. of phosphoric acid per acre, and produced a crop of 29 bushels per acre.

We get in these results some clue to the conclusions derived from practical experience in all countries, that mineral manures are much more beneficial to some crops than they are to others. It is evident that the cereal crops possess a greater capacity for obtaining their food from a poor soil than any of the other crops generally grown.

It is fortunate for the human race that such is the case, as nations must have bread to eat without having to be dependent for it upon the aid of science.—*Southern Planter.*

FARM MEMORANDA.

(From the *Leader.*)

A poultry raiser who condemns the incubator in the *Rural New Yorker* advocates "bringing chickens up by hand." He places each brood in a small box as soon as they are hatched, and allows them no food for one day. As they increase in size he puts them in larger boxes, and finally allows them to run in a small yard. His hens often hatch four settings of eggs in succession.

IT should be borne in mind that it is just as necessary to ventilate drains as it is to put a vent peg into a cask in addition to the tap, when it is intended to draw liquor off; therefore, a square foot or so at the upper ends of the

drains should always be filled to the surface with small rubble stones. Drains thus ventilated, whilst they carry off water more readily in winter, increase the moisture of the soil in summer by the passage of air through them.

CONVERSION OF STARCH INTO SUGAR BY BACTERIA.—At one time it was thought that the peculiar ferment called diastase, which converts starch into sugar, was only produced by germination; later experiments have shown that all seeds contain a certain quantity of soluble albuminoids, which possess diastatic power, and we now know that ungerminated barely will yield an extract very similar in quality, although differing in quantity, from that obtainable from malt. It has recently been shown by J. Wortmann, in a paper published in the *German Journal of Physiological Chemistry*, that bacteria also exert a powerful action on starch and convert it into sugar; and further, that the diastatic action of bacteria is not only due to the organism itself, but also to the secretion by it of a highly energetic fluid capable of converting starch. The action of bacteria on starch is effected by a ferment secreted by them, and which, like diastase, is soluble in water, but precipitable by alcohol. This ferment acts precisely as diastase in changing starch into a sugar capable of reducing cupric oxide, but is incapable of changing albumen into peptone.

NO PHYLLOXERA IN SANDY SOIL.—M. Lalande, the Deputy and Mayor of Bordeaux, France, recently paid a visit to the principal vineyards in the south for the purpose of ascertaining the efficiency of the different modes of coping with the terrible phylloxera. He tested the effects of insecticides. He found the vineyard of Baboulet near Beziers, belonging to M. Jaussan, president of a syndicate for operating with sulphide of carbon, in a very satisfactory condition. He then visited six other vineyards, and everywhere found luxurious vegetation and abundant fruit. At Valantres the Comte de Turenne's property, where American shoots have been employed with great success, all the vines are heavily laden with magnificent grapes. At Aigues-Mortes M. Lalande found all the sandy soils planted with French vines in a flourishing condition, demonstrating the revolution which has resulted from the discovery of the impotence of the phylloxera against a sandy soil. Lands which a few years ago would not have fetched 100 f. (20 dol.) a hectare are now worth 10,000 f. (2,000 dol.).—*Exchange.*

EGGS.—There is nothing more strengthening and nourishing than eggs as an article of diet, and farmers ought to indulge in the luxury of eating them. Not infrequently the eggs are saved up and sold when not as much nutriment can be purchased with the money they are sold for. Four eggs contain more nutriment than a pound of beef steak, and will give more strength, and a person will not tire of egg diet as quickly as he will of fresh meat. They never distress the partaker, and if properly cooked can be eaten with perfect safety. For an invalid there is nothing more wholesome than a raw egg beaten up with a little sugar and stirred into a glass of milk, and taken before breakfast gives strength and health. Boiled eggs are more wholesome than fried ones, and egg sandwhiches are a splendid dish, taken either hot or cold, and especially suited for lunch or picnics. Omelets, poached eggs or boiled eggs cut in slices and a cream gravy poured over them are splendid substitutes for meat at breakfast. Custards and puddings are good changes in the bill of fare, and much better than pies for hot weather, and eggs are an important item in their manufacture.—*Alta California.*

A notable part of the proceedings at the session of the New Jersey Horticultural Society, in Camden, was a successful market gardener's report of four years' experiments with *fertilisers and modes of application.* In one instance, as a mixture, he used 25 loads of stable manure and a ton of bone, or of some other commercial brand, at a saving of about 20 dollars per acre over the use of manure alone. Another combination was 25 bushels of poultry droppings, 400 lb. each of cotton seed meal, plaster, fine bone metal and sulphate of potash, and 10 bushels of muck, making about 1½ tons, at a cost of about 17 dollars per ton. This gave as good results as bone meal and different brands of fertilisers side by side, at a saving of fully 20 dollars per ton. In applying fertiliser alone he used from 1 ton to 1½ tons to the acre in spring; barnyard manure was applied in winter on all ploughed ground. By this process he increased his receipts from 1,750 dollars per year to 7,300 dollars. By high manuring and through tillage the crops were larger, one to two weeks earlier, and, being of quick growth, were of better quality, found an early market, ready sale at good prices and a fair profit, and by the time the market was overstocked his crop was harvested and the same ground ready for a second crop, the one manuring serving for both.—*New York Tribune.*

FERMENTATION.—Fermentation is a chemical process which is by no means popularly understood. To the dairy man it is a bugbear of no small proportions, the more so because he has been taught something of its destructive properties, and has learned to consider it something in the same light as children think of and fear the bugaboo of the nursery. But there is nothing connected with the business of daiying in all its branches that should be better understood. Fermentation is a chemical change which varies as the substances affected by it differ. Generally it may be considered as a change of organic substances, in which their elements are broken up and combined in new compounds. Particularly it may be distinguished as saccharine, when starch and gum are changed into sugar; vinous when sugar is changed into alcohol; acetous when alcohol is changed into acetic acid; lactic when lactose, or milk sugar, and glucose, or grape sugar, are converted into lactic acid; viscous when sugar is converted into mucilaginous substances; and putrefactive when nitrogenous matters are decomposed into substances containing ammonia, nitric acid and other gases. There is also a butyric fermentation which may be produced in milk or cheese by the addition of chalk, or may go on under the presence of certain germs, but this sort of fermentation is generally included under the generic name of putrefaction. All these changes are caused by the development of special forms of fungi, which, however, have a somewhat close relationship, and have been considered as all varieties of each other. Hollier especially maintains that the forms which accompany mildew also induces fermentation and putrefaction, and common experience in the dairy corroborates this belief. Fermentations, under whatever conditions and character they may occur are all purely chemical reactions, and do not all necessarily destroy or cause the destructive decomposition of the substances affected. It is necessary to realise this fact in considering the chemical changes which occur in fermenting substances, especially those which enter into consumption as animal or human food.—*San Francisco Weekly Chronicle.*

HOLING IN COFFEE-GARDENS.

BY COUPERUS.

(Translated from De Indische Gids.)

In laying out either Government or Private Coffee-plantations in Java of late years, holes are frequently dug 1 or 1½ ft. cubic, and even larger, in which the small coffee-trees about half a foot in height, with a pellet of earth of the size of one's first at the root, are planted.

They who have these planting-holes dug, affirm that the coffee-trees planted in them thrive better than in grounds where are no planting-holes, and that therefore these *must* be made.

To the first part of this assertion no objection can be made; for as the soil in such holes—at least in the beginning—is always loose, (except when more earth is pressed into them than was dug out) and sometimes also *better* than the surrounding soil—that is when the earth dug out is supplanted by more fertile soil, or else when the former is rendered better by admixture with manure, leaf-mould, etc.—then it is very natural that the seedlings taken from the nurseries will thrive vigorously in these planting-holes.

Such holes, however, are *quite unnecessary* in soils that are by nature loose and friable, namely, when they consist of a stratum of rich humus, or in the case it is composed of clay mixed with much humus and a large proportion of sand, decayed bits of lava and pummice stone; such as the soil of many volcanic grounds, overgrown with large woods, or thick *glagah, honjé, banana*, etc. In such light, humid, and at the same time fertile soils, which, with a sufficient depth of the upper layer, enjoy an altitude of more or less 300 feet above the sea-level, a good situation as to the sun, and a due protection against gusts of wind or gales, are the best coffee grounds in Java, and into which the roots of the

freshly planted seedlings easily penetrate, it is *decidedly superfluous* to make such large planting-holes.

Here it is quite enough to dig holes just large enough for the roots of the seedlings to have sufficient room, while the side-roots must of course be spread out, and the tap-roots planted straight downwards.

Soils of a loose and fertile nature ought, if large crops are desired for many years, to be kept in this state, and this is only possible by strictly observing the following directions:—

As soon as the ground beings to get hard by the constant trampling of the coffee-gatherers, it must be turned up well, *at least* one foot deep, which renders it very easy for air and moisture-dew and rain to penetrate; for the uprooting of all the weeds growing in it, even those that have deep and far spreading roots, such as *glagah*, *alangalang*, *loempiangan*, and lastly for dispersing, catching and destroying all creatures injurious to the coffee-culture, and more or less dangerous to men, such as crickets (gasir), mole-crickets (andjieugtanah) larvæ of beetles, field-mice, snakes, scorpions, millepedes, wasps, etc., etc. Clear the ground properly of all weeds that thrive at the expense of the coffee-trees, and prevent as much as possible their producing seed.

The eradicated weeds that soon decay must be used as manure, so that they may partially restore to the soil what they have extracted thence; they must be spread round the coffee-trees, where proceeding to rot, they keep the ground humid in dry weather, and are gradually converted to humus.

It is still better to apply them as *green manure*, by working them into the ground round the roots of the coffee-trees; but never do this with such weeds as are apt to shoot up anew from their roots, as for instance *alang-alang*, *loempiangan*, *glagah*, etc.

Such weeds must be removed from the gardens and put in heaps on the garden-walks to dry or decay, when they can be used as manure for the coffee-gardens. The washing away of earth on sloping grounds must be guarded against as much as possible, in order to prevent impoverishment of the soil; so the necessary water-holes must be made between the rows of coffee-trees on gently sloping grounds, in which the earth and humus washed away will collect and so be preserved in the gardens.

In more steep grounds the coffee-trees must be planted on *well-made* terraces, that is, on such whereof the area to be planted is level, and tho slopes rather more slanting than the natural talus of the ground on which they are made, in order to prevent the crumbling down of these slopes:

Manure the coffee-gardens well, even after every crop; and when this has been very abundant, proceed to manure it abundantly, for to wish to extract much from the soil without annual and plentiful manuring, is no economy, but decidedly a system of depredation, which must in the long run impoverish the richest soils.

A judicious manuring is the best means to preserve fertile soils, though yielding great crops, from impoverishment and exhaustion, and it is not difficult to effect; but to render bad or impoverished soils fertile generally requires a great deal of time and much money.

Fertile soils that have been constantly properly manured, and are not washed away, can yield for a number of years large crops, for their fitness to produce coffee will decline but slowly.

Grounds in which the coffee-trees, to thrive lustily, *must* be planted in large holes, as for instance firm soils, where water will not easily penetrate, and clayey soils are quite unfit for coffee-culture, for on such grounds these trees are either relatively short-lived, or they bear poor fruit. If in such soils holes are made and coffee-trees planted therein, then they will often, in a shorter or longer time, show yellow leaves, languish and die away.

This will even frequently happen if the holes are filled with fertile loose earth. The reasons are as follows:—

As the rain-water, collected in the water-holes, cannot readily penetrate the close hard soil, it remains there for a greater or shorter length of time, especially when the bottom is covered with a deposit of slime or mud, it keeps the soil, in which the roots are to spread, too humid, nay, will make it miry, by which it sours, so that the roots languish.

The consequence is that the coffee-trees being insufficiently nourished, languish and finally perish; for though they are tolerably hardy plants, requiring moisture and able to bear a good deal in a genial soil, yet they are not able to stand long or often in stagnant water, or in slush.

If the earth, dug out by holing, be returned without being first mixed with manure, decayed leaves, or such like, it will soon regain its primitive hardness by gradual rains and by its own weight, and this is not promotive of the growth of coffee-trees which require a soft and friable soil.

If holes are made in a gravelly soil, through which the water easily penetrates, and they be filled with loose earth, the seedlings planted in them will thrive well, as long as they draw sufficient nourishment from that earth; but when the roots have grown so as to abut against the hard surrounding soil, they will begin to languish. For the roots, not being able to penetrate the surrounding soil, will go on extending themselves in the fertile, loose soil, till they get packed close like in a pot, and will not be able to yield sufficient nourishment to the coffee-trees.

These results are also observable when the coffee-trees are planted in loose fertile earth in holes made in clayey, loam, or marl (*tjadas*, *whadas*) grounds; for their roots will continue to grow in this earth, rather than seek nourishment from the surrounding ground, which is very unfit for coffee-culture.

If planting-holes are quite superfluous in good coffee-grounds, they are of little or no use whatever, in hard, clayey, loamy or marl and gravelly soils. By making large deep holes in such grounds, and filling them with fertile friable earth, coffee-trees may very well be planted in them, and they may yield large crops; but a person, who, after making such unsuitable ground fit for coffee-culture, sets about laying out coffee-plantations on these grounds, is half ruined before he begins this work. Though it is imperative for the tiller of the ground to assist nature in preserving the fertility of the soil, yet he would act very folishly if he wished to force nature, for as a rule this is never done with impunity.—*Indian Mercury.*

DR. REDWOOD'S PROCESS FOR LIQUID EXTRACT OF CINCHONA.

BY A. J. COWNLEY.

The great difference between the opinions expressed in reference to the process suggested by Professor Redwood for the preparation of liquid extract of cinchona bark, in the course of the discussion that took place after the reading of his paper, is sufficient evidence that there is room for further investigation of the subject, and this view was indorsed by the impression entertained by one of the speakers, "that they knew very little about bark." In any case it appeared desirable to ascertin how far the process now suggested by Professor Redwood as a substitute for the one which is official in the present British Pharmacopœia is calculated to realize the objects which he has defined as being most important, and whether it is a substantial improvement on the existing process. I have therefore carried out some experiments to determine these points, and have obtained results that I will now proceed to describe.

As regards the kind of cinchona bark operated upon, I have acted upon Professor Redwood's decision that East Indian succirubra bark is the best to be used for preparing a liquid extract, and though not fully agreeing with this opinion, have not now ventured to offer any objection to it, since I am not aware that the "previous observations"* which led Professor Redwood to that decision have yet been made public. Some difficulty was experienced, however, in selecting for the purpose of my experiments "red cinchona bark of good average quality." In the absence of any criterion to serve as a guide in this respect and having regard to the extreme variability of this kind of bark,—the contents of alkaloids ranging from less

* Clearly there is a growing "fashion" in favour of red bark. We may, however, take the opportunity here of remarking that among the various recommendations of Indian succirubra bark, the one put forward by Professor Bentley, of its being "the sole bark recognized in the German Pharmacopœia," seems to be scarcely in accordance with the qualifying term "*præcipue*," which is used in that work.—ED. PHARM. JOURN.

than one per cent up to more than ten per cent—as well as the absence of any definite or recognizable relation between the external characters of a sample and the amount of alkaloids contained in it, I concluded that it would be best to operate upon bark of previously ascertained alkoloidal contents, and to choose such as contained a medium percentage, as shown by the following figures:—

	Per cent.		Grains per lb.
Quinine	2·1		147
Cinchonidine	1·6		112
Cinchonine	2·03	or	142¼
Amorphous alkaloid	1·00		70
Total alkaloids	6·73		471¼

Liquid extract made from this bark by a process capable of effecting the entire removal of the alkaloids, and standardized so that 1 fluid ounce would correspond to 1 ounce of the bark, ought, therefore, in accordance with the above figures, to contain about 29½ grains of total alkaloid per fluid ounce, with the several alkaloids in the following proportions:—

	Grains.
Quinine	9·2
Cinchonidine	7·0
Cinchonine	8·9
Amorphous alkaloids	4·4
Total alkaloids	29·5

This would be rather more than 5 per cent—the proportion recommended by Professor Redwood; but for the purpose in view the bark was considered to be sufficiently near to the proper standard.

In operating upon one pound of this bark in the manner directed, I found that when 10 pints of liquid had passed through, the percolate still gave a precipitate when mixed with caustic soda in excess; the operation was therefore continued until the percolate had ceased to give this reaction. On reaching that point 13¾ pints of liquid had passed through. The percolate was sensibly acid, even while thus dilute, and when evaporated down to one pint was much more strongly acid. On cooling and diluting the liquor with water it deposited some brown flocculent material, which, when separated by filtration, washed and dried, was found to weigh 27¼ grains and to contain 1·1 grain quinine with traces of the other alkaloids. The filtered liquid evaporated to dryness left a residue of solid extract weighing 4½ ounces, which was found on analysis to contain 12·96 per cent total alkaloid.*

According to the directions given by Professor Redwood in his paper for preparing the liquid extract from this solid extract, it is easy either to obtain a preparation that shall contain 5 per cent total alkaloid, or one containing in a given bulk exactly as much total alkaloid as the corresponding weight of bark operated upon. But to fulfil both these conditions it would be necessary to use bark containing exactly 6·25 per cent total alkaloids. In the present case, for instance, 1 ounce of the bark contained nearly 29½ grains of total alkaloids, and by dissolving to the volume of a fluid ounce as much extract as contained that quantity of total alkaloids (227½ grains), of course the fluid ounce of liquid extract would to that degree correspond to 1 ounce of the bark it was made from, and would contain 6·73 per cent of total alkaloid. To bring it nearer to Professor Redwood's standard of 5 per cent, 168¾ grains of the dry solid extract was dissolved to the volume of one fluid ounce, and on analysis the product gave:—

	Grains.
Quinine	5·89
Cinchonidine	5·90
Cinchonine	5·69
Amorphous alkaloid	4·39
Total	21·87=5 per cent.

By comparing these results with those furnished by the analysis of the bark operated upon, it will at once be seen that the relative proportions of the alkaloids are different as compared with the orginal bark, and that there is in the extract a relative deficiency of quinine, together with a relative preponderance of amorphous alkaloid. There was, therefore, some reason to infer that the extract did not adequately represent the bark from which it was made, inasmuch as it contained a smaller proportion of the most valuable and important alkaloid quinine, and a much larger relative proportion of the less valuable amorphous alkaloid, which is by some considered to be objectionable from a medicinal point of view. In addition it will be seen that the quantity of solid extract requisite to make one fluid ounce of liquid extract representing one ounce of the bark, was very much larger than the quantity obtained from one ounce of bark, or 227½ grains instead of 115½ grains.

This leads to a consideration of the further desideratum, that in preparing liquid extract "the bark should be exhausted of its alkaloids by the process adopted," and it must be pointed out that as yet no evidence has been furnished that the suggested process is capable of effecting such a result. The device just referred to, of taking as much solid extract as contains a desired quantity of total alkaloids in order to make a certain bulk of liquid extract, is one very safe to rely upon for standardizing the amount of total alkaloid in the latter preparation; but since it has no kind of connection with the entire removal of the alkaloids from the bark used, the efficacy of the process in this respect must be tested in another way. In order to obtain some evidence on this point the total quantities of the several alkaloids in the solid extract above referred to were computed on the basis of the analysis and compared with the quantities contained in the bark from which it was made, as follows:—

	One pound of bark contained Grains.	4½ oz. of solid extract contained Grains.	Deficiency.
Quinine	147	64·57	82·43
Cinchonidine	112	64·70	47·30
Cinchonine	142¼	62·30	79·95
Amorphous alkaloid	70	48·03	21·97
	471¼	239·60	231·65

It is evident from these figures that there was not only a large deficiency in the amount of total alkaloid, but that the quantities of the individual alkaloids showed dissimilar deficiencies, and that, in short, while only one-half of the total alkaloids had been extracted from the bark it was chiefly in regard to the more important alkaloids that this loss was most considerable. Evidently, therefore, the proposed treatment with hydrochloric acid does not furnish a preparation that can be considered to represent cinchona bark in such a manner that a fluid ounce shall contain all the valuable medicinal properties of an ounce of that drug.

In making liquid extract by this process the bark consumed is only half represented as regards total alkaloids, for, as already shown, it would be necessary to take the solid extract from nearly two ounces of bark to make one fluid ounce of liquid extract containing as much total alkaloid as one ounce of the bark, while beyond this the total alkaloid in the liquid extract so produced would be much inferior, as regards the relative proportions of its constituents, to that actually contained in the bark itself.

To obtain further confirmation of this result the residual bark was submitted to analysis, and it was found to contain 4·49 per cent total alkaloid. The following table

* I was unable to obtain satisfactory results in the analysis of this extract according to the method directed by Professor Redwood. On treating 20 grains of the extract with caustic soda, a slimy precipitate was thrown down, and the liquid became so thick that it could not be filtered readily. After washing and drying this precipitate, it weighed only 0·92 grain, though it was only in part alkaloid, while the quantity of alkaloid was found by another method to be 2·59 grains. Part of this deficiency was in all probability owing to the viscous state of the extract solution when mixed with caustic soda, but in part it was a consequent of the solvent action of the water present. This was ascertained by operating upon a quantity of dry quinine sulphate containing 2·59 grains of alkaloid dissolved in one fluid ounce of water, and mixed with three fluid drams soda liquor and washing the precipitate so obtained. The dried precipitate obtained weighed only 1·97 grain showing a loss of 0·62 grain.

gives a general *résumé* of these results, from which it will be seen that the residual bark contained nearly as much alkaloid as had been extracted by the process, and that as regards the relative proportion of quinine it contained it was even better than before treatment:—

	One pound of the bark contained	Precipitated by water 27·3 grains	Solid extract of red cinchona 4½ oz.	Residual bark contained
	Grains.	Grains.	Grains.	Grains.

—*Parmaceutical Journal.*

In the following number of the *Pharmaceutical Journal* Mr. Redwood writes:—

LIQUID EXTRACT OF CINCHONA.

SIR,—In the experiments I made for the purpose of obtaining data on which to found the process I have suggested for liquid extract of cinchona, a sample of succirubra bark was first operated upon which, tested by De Vrij's method with lime and alcohol, yielded 4·8 per cent. of total alkaloids; and this in No. 60 powder, when treated as I have described with hydrochloric acid and water, and reduced to a dry extract, gave by precipitation with soda an amount of alkaloid corresponding to 4·3 per cent of the bark used. In this operation not only was the percolated liquid acid, but the marc at the end of the process was slightly so also, and viewing this in connection with the fineness of division of the bark and the known action of hydrochloric acid as a solvent of cinchona alkaloids, the result did not exceed what appeared to me reasonable to expect. I took the near approximation of the amount of alkaloids in the extract to that in the bark yielding the extract as indicating a practical exhaustion of the bark, although, no doubt, further evidence would be looked for to establish complete exhaustion, especially as the method I adopted for estimating the alkaloids in the extract is not a rigidly exact one. My object was to devise a method as little complicated as possible and suitable for adoption by pharmacists generally, but the desire to submit such for criticism at a pharmaceutical meeting before the meetings had terminated for the season rendered it necessary to leave several parts of the investigation to be subsequently completed.

Since the publication of my paper I have repeated the process upon further samples of East Indian succirubra bark with results similar to those I have already recorded. The barks I have used have contained from 4·8 to 5·5 per cent of total alkaloids, and with these I have found that when the percolated liquid has reached a quantity corresponding to ten or, at most, eleven pints of percolate from a pound of the bark, it has ceased to give a precipitate with soda. The marc, on being then treated with fresh hydrochloric acid, although yielding a solution which gives a dark brown extract with soda, some of which may be percipitated, has afforded me no distinct evidence of the presence of alkaloid. By a more searching process, however, with lime and alcohol (De Vrij's method) a small quantity of mixed alkaloids may be extracted, amounting, I have found, to about a tinth part of the alkaloids originally present in the bark, as determined by the same method. Thus a bark containing 5 per cent of alkaloids, after being exhausted by the hydrochloric acid process, yielded 0·53 per cent of additional alkaloids, the same method of estimation being adopted in both cases.

The results obtained by Mr. Cownley, and published in last week's Journal, appear to me to be explicable only by assuming that the sample of bark he has operated upon differed very much from any of those I have employed. It was richer in alkaloids than any of mine, but I do not think that alone would account for the results obtained by him. I have not yet worked on barks so rich in alkaloids as the one he describes, but am prepared to find that some modification of the process, especially in regard to the proportion of hydrochloric acid, may be necessary to meet the requirement of very rich barks. I attach importance to the degree of comminution of the bark in treating it by this process, and the fact that Mr. Cownley found it necessary to continue the percolation much further than I have done has raised a doubt as to whether he used the bark in sufficiently fine powder.—T. REDWOOD.

THE RESIN INDUSTRY IN THE LANDS DEPARTMENT.*

BY A. RENARD.

The Landes department is the most important centre in France for the production of resin. This large triangular space of about fourteen thousand square metres, bounded upon one side by the ocean, and on the others by the Adour, the cultivated heights of the Lot et Garonne department, and the vineyards of Bordeaux, is an ancient bed of the sea, covered by sand of the Pliocene age. The sandy masses, which in many places are more than eighty metres thick, contain a few beds of clay; but at only a slight depth there occurs a compact layer, termed "alois," which is traversed with difficulty by the roots of trees, and which is one of the greatest obstacles to forest vegetation. In former times the rain-water, retained by this compact layer of sandstone, remained upon the soil, and transformed the surface of the Landes into a vast marsh; but since then numerous drainage ditches have been cut and convey the surplus water to the pods on the shore. In this way the surface has now become almost dry, the marshes have disappeared, and the inhabitants of these districts are no longer compelled to raise themselves on stilts to traverse the vast stretches of land, which formerly were impassable to ordinary pedestrains.

There is no doubt that before the middle ages the greater part of the Landes was covered with forest, at least upon the borders of the sea; but through the improvidence of the inhabitants these woods had been destroyed, and the sand had commenced its invading march from the sea coast, threatening to swallow all that it met upon its way. The first attempts which were made to reclaim the "dunes" date from the commencement of the eighteenth century; but it was Brémontier who, between 1787 and 1793, definitively solved the problem of the plantation of the Landes, he succeeding in consolidating more than 250 hectares of shifting "dunes." In the present day an immense forest of pines covers all this vast extent of territory, formerly uncultivated and marshy, and forms an impassable barrier to advance of the "dunes" from seaward.

The maritime pine is the tree chosen, to the exclusion of almost all others, by the Landais cultivators, and its reproduction is effected either from seeds or from cuttings; but the finest trees are those obtained from seeds, and this is the method generally followed. The sowing takes place naturally. Every four or five years a clearing is made by cutting down the least vigorous of the young trees so as to allow the others to develop under the most favourable conditions, and at the end of twenty-five or thirty years the trees are about one and a half or two metres apart. Those which at this stage still require to be removed are bled to death. This operation consists in making two large gashes on opposite sides of the tree, the turpentine that exudes being collected by one of the methods described subsequently. Under these conditions the tree is quickly exhausted, and at the end of four or five years is cut down. Eventually a final selection is made of the finest trees in the *pignada*, which are to be preserved for regular working, care being taken that they shall be equidistant at about eight metres; all the others are then bled to death and cut down at the end of from five to seven years. When the trees selected for preservation, which are called "*pins de place*," have attained a diameter of 30 to 35 centimetres they are ready for working.

By means of a sharp blade, slightly curved and fixed perpendicularly at the end of a wooden handle, an incision is

* From the Moniteur Scientifique, vol. xiii., p. 945.

made at the base of the tree on the side facing the east, and this is retouched every three or four months. The cutting is commenced in April and continued until the end of September, during which time it should reach a height of about half a metre. Care, however, is taken early in the season, about the beginning of March, to define the extent of the incision by removing the external surface of the bark from the part of the tree which is to be denuded. The following year the incision is continued upwards, and afterwards, for five consecutive years, until a height of two and a half or three metres is reached. A similar operation is then commenced on the side of the tree exposed towards the south, and by the time this has had its turn a return can be made to the first incision, which has become cicatrized. When the operation is well conducted a tree can be thus bled during more than two hundred consecutive years (*pendant plus de deux cents années consécutives.*)

Two methods are in use to collect the exudation. The older one, which is the most simple, consists in making a small trench at the base of the tree, in which the runnings from the tree collect. While the incision is near the ground the collection is effected fairly well; but after two or three years, when the incision has attained a considerable length, the exudation reaches the ground with difficulty. Under the influence of wind and sun the greater part of the essential oil is volatilized or resinified, and the collection becomes insignificant. The second method called "Hughes's method," after its inventor, partially avoids these inconveniences, and besides, has the advantage of yielding a "gemme" much more free from soil and vegetable *débris*. It consists in affixing to the tree, by means of a nail, a small pot, which is placed every year under the fresh cut. The turpentine thus caught, having to run a less distance to reach the recipient, is always richer in essential oil than that obtained according to the older method.

The collection of the "gemme" is made every two or three weeks. The pots are first emptied into a vessel of forty or fifty litres capacity, from which the contents are transferred to a large trench in the ground capable of holding four or five hundred litres, from which the casks are filled when required for sale. In October the resin that has solidified on the tree is gathered. This can be added to the other portion for the purpose of distillation, but usually it is kept separately, and sent into commerce under the name of "galipot" or "harasse."

The "gemme" is the primary material for the manufacture of oil of turpentine; it is a mixture, or rather a solution of colophony in the oil. Under the influence of heat the oil is volatilized and the colophony is left as a residue. The industrial distillation of the "gemme" is carried on in small factories usually situated in the midst of the forest. The season commences in the month of May and terminates in October.

On the arrival of the "gemme" at the factory it is decanted into two large wooden vats capable of containing one hundred barrels of 340 litres each. By means of a kind of saucepan fastened to the end of a long wooden staff the material is dipped from these vats and introduced into two large copper boilers, known as preparatory boilers, of six to eight barrels capacity. In these boilers the "gemme" is heated during a whole day over a low fire. The water collects at the bottom, whilst foreign substances, such as chips of wood, twigs, etc., rise to the surface, from whence they are skimmed off and put to drain in straw filters arranged above the second boiler. In the evening the fire is allowed to go down and the boiler is left to itself. In the morning the "gemme," freed in this way from the water that it held in suspension and which frequently amounts to 12 or 15 per cent, as well as earthy and ligneous matters, is introduced into a copper receiver of a fixed capacity of 300 litres. At the bottom of this pan there is a pipe, fitted with a tap, the other end of which opens at about eight inches from the bottom of the still in which the distillation has to be effected. The still is of copper and furnished with a worm that dips into a wooden receiver full of water. Three hundred litres of "gemme" are run in and heated strongly. The oil commences to distil over and at the end of fifteen or twenty minutes about eighty or a hundred litres of hot water are run into the still through a tap fixed in the upper part of it. This addition of water has for its object to facilitate the volatilization of the remainder of the essential oil. The distillate is received in a vessel made of sheet-iron and fitted at its upper part with a capacious pipe, by which the essential oil, being lighter than water, passes off into the casks set for its collection.

When the liquid issuing from the worm no longer contains much essential oil, the supply of water is stopped; the distillation is then continued for a few minutes more and the operation is finished. The yield of essential oil various with the season and is about 15 to 18 per cent of the weight of the "gemme." The exit pipe at the bottom of the still is then opened and the "brai," or resinous residue, is run into a sheet-iron tank, after having been made to pass over a copper plate pierced with holes, so as to eliminate various impurities that it may contain. The apparatus is then ready for a fresh operation, which is commenced without allowing it to get cold. In this way eight or ten distillations are effected daily.

After the "brai" has been allowed to cool for some time it is run into wooden casks, where it solidifies. That which is derived from "gemme" collected by Hughes's method is sent into commerce under the name of "yellow colophony," and that obtained from "gemme" collected by the old method is sold under the name of "brai clair." The resins of inferior quality, or "brais noirs," are obtained by the same method, but are the product of the distillation of the less pure portion of the "gemme" which collects towards the bottom of the preparatory boilers.

Sometimes the "brai," instead of being run directly into casks, is used for the manufacture of resin. In this case, upon issuing from the boiler of the still, it is run into a special vat, and whilst it is still liquid about 15 to 20 per cent of hot water is added, in quantities of 20 to 30 litres at a time. The mixture is stirred energetically with staves until the whole mass has become opaque and thoroughly homogeneous; then it is run through a trough in sand into cylindrico-conical moulds also in sand, where it solidifies. The resin thus obtained is of a pale yellow shade, and under the name of "yellow resin" or "*résine de boutique*," is used in the making of resin candles.

The straw filters, upon which have been deposited all the impurities collected upon the surface of the preparatory boilers, are used for the preparation of a further quantity of "gemme" of inferior quality. They are introduced together with the detritus remaining upon them into a kiln, resembling a lime-kiln, known as a "*four à pègle*." The fire being lighted and a portion of the material burnt, determines the liquefaction of the "gemme," which runs off through an orifice situated in the lower part of the kiln into a receiver containing water. This "gemme," submitted to distillation, yields about 10 per cent of its weight of essential oil.

Manufacture of Resin Oils.

This industry dates back half a century, and at the present time has attained a considerable development. In 1832, M. Dives, whilst distilling "gemme" for the extraction of oil of turpentine, made the observation accidentally that in continuing the operation beyond the point when only colophony was left in the still this was decomposed, giving rise to an oil. He therefore replaced the copper alembics by cast iron retorts, and the mode of distillation which he adopted is the same as is employed at the present time.

Eighteen hundred kilograms of "brai" are introduced into a large hemispherical cast iron boiler, heated over arches, together with 1½ or 2 per cent of lime, added with the object of rendering the oils more fluid. The boiler is covered with a copper dome, which is luted with clay; this is in communication with a worm, also in copper, disposed in a vat full of coldwater. Pine wood is employed as fuel in heating the boilers. The operation is commenced at three o'clock in the morning, the fire being urged strongly at the commencement, and in two or three hours the distillation begins; the fire is then moderated and maintained so until seven in the evening. The distilled products are received in a small sheet iron vessel, having in its upper part a tube by which they can be passed into the casks. At the commencement of the operation water passes over, which is run off through a tap placed in the lower part of the receiver. Afterwards about 25 kilograms of a light fraction are collected, and then nine or ten barrels of oil, each containing 160 kilograms. At the end of the operation the bottom of the boiler is brought to a dull red heat. There remains then only a solid carbonaceous residue, which has to be removed by means of a pick after each distillation

The total yield in the lighter fraction and resin oils is about 80 to 85 per cent; the principal loss is due to the combustible gases which are given off in abundance during the whole of the operation, and which have not hitherto been utilized.

The resin oils thus obtained are not identical throughout the entire distillation. They are distributed generally according to their colour, into three classes: pale oils, blue oils and green oils.

The "pale oils" are the most abundant, the quantity reaching 1,100 or 1,200 kilograms in each operation. They are of a brownish yellow colour and rather fluid. In density they vary between 0·990 and 1·000. They are incongelable, even at very low temperatures. They possess considerable lubricating properties, but present the inconvenience of resinifying rather rapidly in contact with the air, which, together with their odour, has always limited their employment. Railway companies and miners use large quantities for lubricating machinery, after adding 25 to 50 per cent of colza or mineral oil. They are also employed, either alone or mixed with linseed oil, in the manufacture of printing ink.

The "blue oils" consist of that portion of the products which passes over immediately after the pale oil. These oils are more coloured and have a very pronounced blue fluorescence. Their density is about ·990 to 1·000.

Lastly, when the operation approaches its termination, the "green oils" are collected, which are of a still darker shade, and possess a very strong green fluorescence. They are always mixed with a very large proportion of water, from which it is extremely difficult to free them. These oils, like the "blue oils," are more fluid than the "pale oils;" they contain, in fact, a larger proportion of a light spirit, the presence of which is due to the commencement of pyrogenation which the colophony undergoes in consequence of the high temperature to which the distillatory apparatus is submitted.

The blue and the green oils are employed especially as lubricants for waggons used in mines. As to the light spirit the proportion of which amounts to one or two per cent of the colophony distilled, its employment is very limited. It possesses a very pronounced odour, is brownish in colour, and has a density of about 0·950. Exposed to the action of the air it resinifies rather rapidly, similarly to oil of turpentine. Occasionally it is used in the place of oil of turpentine, especially in making up paint for out-door use.

The resin oils, obtained by the method indicated, are usually sent into commerce in the same condition. They are then frequently turbid and slightly opalescent through the presence of a small quantity of water distributed through the mass. In order to render them limpid, M. Durou has proposed to allow them to stand some time in large reservoirs arranged under glass roofing, exposed to the sun. Under the influence of heat and light the oil clarifies pretty rapidly, especially in summer, and at the same time undergoes a slight decoloration. The same result is also attained by a rectification, and for this purpose the apparatus used in the distillation of the colophony is employed. The operation should be conducted slowly. A certain quantity of light spirit is first collected and set aside, after which, the oil distils perfectly clear. This distillation yields very good results; but always occasions a loss of 6 to 8 per cent. The rectified oil has a density of ·972. Several processes have been proposed for removing from resin oils their odour, which in many cases constitutes an obstacle to their employment. Washing with soda, followed by agitation with sulphuric acid, is the process which appears to yield the best results, but this method of purification has not yet received any industrial application.

When a lubricant for carriages is required the "brai" is submitted to a rapid distillation not lasting more than four hours. The oil obtained under these conditions then contains a large proportion of resin, which has been carried over mechanically; it is viscous and thick, and is known as "strong" oil. To prepare the lubricant, one part of slaked lime is suspended in two parts of thin oil from a slow distillation, and one part of the thick paste so obtained is incorporated with four or five parts of "strong" oil. The resin contained in the latter combines with the lime to form a resinate of lime. The paste is stirred well, and then while still liquid it is run into barrels or boxes, where it acquires quickly the desired consistency. These lubricants are sometimes coloured by the addition of powdered pigments.—*Pharmaceutical Journal.*

IN NEW ZEALAND a company is proposed to be formed with a capital of £10,000 for the purpose of establishing the culture of silk, olive, wine, colza, castor oil, and other kindred industries.—*Australasian.*

AUSTRALIAN GUM ACCROIDES.—At the recent Amsterdam Exhibition was shown some resin obtained from *Xanthorrhœa hastilis*, called gum accroides, a native tree of New South Wales. The gum shown was a good marketable sample, worth in Sydney £24 per ton; a few months ago it was sold, in London, at auction sale of gums at more than double that price. The quantity collected during 1882 was over 100 tons; this quantity is very largely in excess of former years. The resin is used in the manufacture of picric acid by dissolving the gum (or rather we should say resin) in strong nitric acid: violent frothing takes place, red vapours are given off, and a dark-red solution is formed, which becomes deep yellow after boiling. This solution is evaporated over the water bath, and the remaining yellow crystalline mass, together with picric acid, contains small quantities of oxalic and nitro-benzoic acids. It is then neutralised with potash and the picrate of potassium is purified by two crystallisations, and then treated with hydrochloric acid, which separates the picric acid, to be again purified by two crystallisations. The amount of picric acid thus formed is about half the weight of the gum to be used in its manufacture. An excellent spirit varnish is made from this gum by adding to about one gallon methylated spirit (cold)—about 2½ lb. gum, about ¾ lb. common resin, and about ½ lb. shellac—then strain through muslin cloth. This varnish must be used upon dry work, and is easily applied to our climate; if found not to answer in cold or damp climates, we would suggest it should be tried in a warm dry room. The gum is used for staining wood, and also in the manufacture of sealing-wax, brass lacquer, and Japan gold size.—*Public Opinion.*

ROOT PRUNING.—There is a Mr. Kynaston, somewhere towards Wales, in England, who has made for himself a reputation, and to a certain extent become an authority, upon the subject of root pruning. He managed always to to get a crop of fruit, whilst his neighbours got very little one year, and a fair crop the next. This went on for about twenty years, and some people began to think there was witchcraft or diablesie in it. However, he published what he called his secret, and it turned out to be nothing else but rootpruning and manuring. He holds a theory that every fruit tree possesses three kinds of roots—those which descend keep the tree firm in the ground and supply moisture; those which traverse long distances near the surface add moisture to the growth of the limbs and foliage, and those which form close to the trunk or pole and help very considerably in the formation of fruit. The first and the last are to be encouraged—in his opinion—but the long stretching wood-forming roots should be discouraged. Therefore, he digs a circular trench at a distance of four to eight feet from the pole or trunk—according to size—about a good spit deep. Then he takes a pickaxe or mattock, and breaks up the subsoil in search of the long roots, which when found he cuts off. He puts manure into the trench along with the earth, and is careful to manure the ground beneath the branches of the tree, which has the effect of greatly encouraging the production of the small fibrous roots that he believes are chiefly designed for the production of fruit. There is one thing in his theory which will perhaps not bear too close criticism. Why not encourage the production of the fibrous roots by the application of manure near the bole or trunk without destroying the long roots? However, he is credited with having been very successful in his practice, and the hint his worth consideration where owners have trees that do not bear satisfactorily.—*Adelaide Observer.*

CACAO, TRINIDAD AND WEST INDIES.

Arima Cacao Estates, Trinidad, 27th Nov. 1883.

A story exists of a worthy gentleman who had returned to England after a long residence in Central Africa, that, when asked by people about this unknown quarter of the globe, he vouchsafed his questioners no other than this stereotyped reply: "*It was chock-a-block full of niggers and darned hot.*" The same may be said about the West Indies, from the time you strike Barbadoes.

From there, I went to Venezuela landing at La Guayra, the port of Carácas. A railway much like the one in India from Saligori to Darjeeling connects them, making a rise of 3,000 feet and more. Carácas is a nice city, but the Archbishop was dying whilst I was there. I found it dull rather, and stayed at Macuto on the coast—a sort of Brighton—in preference. The cacao there is of very fine quality and prepared for shipment with red clay—a very simple operation which prevents it from getting worm-eaten. The best cacao here is that of Guyria, the bean rounder than the Trinidad sample and perceptibly sweeter, and the required aroma from the curing is one difficult to describe, but once known easily detected again. I found in Trinidad, to which I came, calling in at all the coast ports, that they had not studied this point, so important in the London market, sufficiently and that the planters there went too much by chance and rule of thumb as regards the curing of the bean. If in the sweating cistern you use iron for the perforated bottom, it is apt to discolor, not only the beans in contact with it, but the whole layer. If the broken bean shows even a shade of purple, it is bad curing. I may be going over ground already prospected by Mr. R. B. Tytler during his visit here, but I may say that for shade trees (and the planters here invariably plant under shade) the favorite is the immortelle (*Erythrina ombros*), that is for localities naturally dry; but if the ground is any way swampy, the sand-box (*Hura crep.*) is preferred, as it is supposed to drain the land of superfluous moisture.

Mr. Gaston de Gannes, with whom I am staying, is one of the oldest planters hereabout, and he plants first cassava and maize between the rows to act as shade until the immortelles grow a bit.

The unscientific way they plant here may be imagined from the fact that no rainfall record is kept, and the Government P. W. Department could give me no return of anyplace except that of their head-station in the capital, Port of Spain.

The labor is very mixed. Of Indian labor, Bengalis are to be found most as contractors on plantations, while the chief sellers of fruits &c. in the towns, after West Indian niggers, are Tamils who, strangely enough, are not so much liked by planters as the Bengali laborer.

On the plantations the coolies weed not with hoes, but only cut down the undergrowth with cutlasses. A mutiny of laborers armed thus would be a serious matter. The other day in the jungle I met a girl so armed, and with her hair streaming down all over her shoulders and her wild look she would have served as a fine model to an artist for a Judith; "a great fear" as 'Ouida' would say, came over me,—a sensation novel to me in presence of the sex!

The people here are very discontented with their Government, and the Governors selected for them by the home authorities. Sir Arthur Gordon however has a good word from everyone for his rule while here; an administration described as vigorous and go-ahead though opinionated. I did not expect to have heard such praise. How easily we in Ceylon formed a contrary estimate of him in anticipation of his arrival!

I went over the Pitch Lake, which is the chief natural wonder here, with the paymaster of the workmen. They work out the asphalte at the parts where the water is not boiling, simply with picks and shovels,—no dynamite or other advanced appliances.

The trip down there by steamer is rather pretty *via* San Fernando, a nice town built with the strange infatuation that characterized the people of Pompii, on the side of an old volcano.

To sum up the state of this part of the world, Ceylon ought to beat it all round, even in the matter of cacao. The disadvantages of high-priced labour here and the further taxes planters incur for cooly medical aid and Government philanthropy must deter the extension of agriculture.

Havana, Cuba, Christmas.

The look of this place disappoints me, and, although this is the cold season, the smells are atrocious both in harbor and ashore. I waited a fortnight at St. Themas' and passed over to the island of Santa Cruz in the "Vigilant," a schooner which has quite an eventful history having been a pirate craft more than once. Both islands belong to Denmark. Labour troubles unsettled Santa Cruz some years ago, and the coolies, chiefly West Indian niggers, fired the plantations and ruins still mark the scenes of the outrages. In one Scotch gentleman's house where I was, a monument of the riots is a picture in the drawing-room riddled with bullet-holes. The troubles arose suddenly from gangs of niggers in town getting drunk and being smitten with pyromania. I am assured that there was no planned insurrection, though they say that British niggers from Barbadoes and Jamaica (who are looked upon as bad characters generally in all these islands) were the ringleaders. Scarcity of labor and high rates retain affairs in a semi-alive condition.

We leave for Mexico today, and I look forward to my travels through it to the Pacific Coast as likely to prove the most interesting of any until I arrive in Ceylon again about June probably. So long, yours truly,

W. G. SANDISON.

MR. O'BRIEN ON COFFEE AGAIN.

The gentleman who recently shewed so conclusively that Ceylon and Indian planters know nothing of the cultivation, has again addressed the Secretary of State about the preparation of the berry. In roasting, it will be seen, the process is to be continued until a spark of fire appears and then the berries become soluble by a fixed law! The Secretary of State deemed this wonderful letter worthy of being forwarded to the Madras Government and the latter have printed it in their records, as follows:—

Letter from G. O'Brien, Esq., to the Under-Secretary of State for India, India Office, London, dated London, 6th March 1884, No. R.S. & C. 126.

As a continuation of my former article, dated 18th January 1884, on "Coffee Plantations in India," I now append the enclosed, which please forward to the Government of Madras, to whom it will certainly be found useful, as well as to the other presidencies of India.

MEMORANDUM

"Showing the causes of destruction of the Coffee Plantations in Ceylon and Madras, India, compared with other methods employed in the United States of Columbia and other parts of South America."

The ordinary method practised in preparing the coffee-berry for exportation is by previously removing the external pulp and parchment for purposes of inspection and other commercial conveniences, but this plan diminishes its fine aromatic flavor and solubility, causing enormous waste, and

thus it is worthy of consideration whether it would not on the whole be an absolute economy to dry the berry in its primitive state as plucked from the shrub, and thus deliver it for domestic use, as is practised in Bolivia. In a dry climate of dear labor and no machinery the expensive process of "pulping" has been found to be unnecessary and detrimental. Thus on the western coast of South America, the Bolivian coffee "Café de Yungas" is always sold in its primitive state unpulped and realizes as much as four shillings per pound, and is not inferior to the finest mocha, whereas the coffee of commerce is there only worth one shilling per pound. As "unpulped" coffee retains its essential flavor in contrast to the naked bean, and consequently badly roasted, green, and raw-flavored coffee of commerce, underdone in the centre of the berry even when over-roasted outside, and for the following reasons, thus well-flavored coffee should be heated throughout to about 390° Faht., as then only it becomes soluble by a fixed law, and by means of its external covering, defending the interior from sudden heat, and on becoming carbonised, falls to the bottom of the earthen pipkin or roaster used, and being a non-conducting substance, still defends the now naked bean which should be well moved, and when the powdered pulp attains the heat of 400° Faht., a dull spark of fire is visible and is the signal that the coffee is roasted. The ordinary rule with commercial coffee in roasting being when "vapor arises," being the essential oil escaping, and it will be found on this experiment being practised in India that much more depends upon the proper roasting of coffee than on the quality of the berry, and for home consumption in India the idea cannot but prove a luxury and economy. (Signed) G. O'BRIEN.

London, W., 6th March 1884.

To the Hon. the Under-Secretary of State for India.

REPORT ON THE EXPERIMENTAL GARDEN, SILAM, IN THE TERRITORY OF NORTH BORNEO.

SILAM, 10th January 1884.

MY LAST REPORT ON THE GARDEN was in May last, and consequently a great change has, as would be expected, taken place since that time, both as regards the extension of land planted and also in the growth of those plants already established, and which I will refer to below in due order.

THE HEALTH OF THE COOLIES, which, at the commencement of the garden gave great trouble, is now most satisfactory, cases of fever being few and far between. I find the Malays are much hardier than Chinese, and have therefore employed none but them; and find no difficulty in getting as many as I require.

THE SURVEY of the garden, which was urgently required was accomplished two months ago, and shows that there are 83a. 3r. 5p. felled and 46 acres planted; made up of five small clearings (as per plan enclosed), with carefully left jungle-belts between each, to keep the products protected from wind.

ROADS AND DRAINS.—The whole garden has been thoroughly roaded and drained, and where necessary bridges have been built.

DISEASES, PESTS, &c.—I have carefully looked for signs of disease among the different products, and am glad to say I can discover none; while pigs alone give us a little trouble. I consider the present cultivated acreage will be sufficient for present requirements. Several products, such as nutmegs, divi divi, &c., have to be planted some distance apart, but allow space for some other product to be planted between them, provided the produce is of small dimensions.

CLEARING No. 1. EXTENT 12A. 3R. 8P.—The greater portion of this clearing consisted of cacao (yellow and red variety) planted under shade, but it was soon apparent, from the difference of the growth of that in the open, compared to that under shade, that the latter method was unsuitable, if not hurtful, to the growth of cacao, and so I had the jungle all felled.

CARDAMOMS.—About an acre is planted under shade with this valuable spice, there being two varieties, viz., Malabar and Burmese, both of which have fairly started and are growing well. There are still a few more thousands in the nursery and land ready for their reception, and they will be planted out directly the weather is favourable.

COFFEE ARABICA.—About an acre is planted with this product, the seed having come from plants (Bornean) planted at Tampasuk by Mr. Dobree, and are growing well. During the last month or so the plants have been attempting to blossom prematurely, but the incessant rain turned the blossom into wood, now, however, the weather has changed, and a blossom will have every chance of setting.

SHADE TREES.—The Albizzia or Java shade tree, of which we have several planted, have grown at an enormous rate, and are, as would be expected, very brittle. They are, however, handsome trees, and fulfil their duty as shade trees.

I should like to see some of these planted along the roads at the different stations, but until there is some responsible person at each station to look after their welfare, it cannot be accomplished.

THE DIDAP* is another and more sturdy shade tree, and is very useful for growing pepper vines up. I have, however, only a few plants, having been disappointed in getting seed; cuttings, however, I find strike easily.

ILANG-ILANG.—Of these plants only one survived transplanting and is now a healthy looking shrub.

CLEARING No. 2, IN EXTENT 12A 0R. 30P. is unplanted, and for the present abandoned.

CLEARING No. 3. IN EXTENT 13A. 1R. 30P.—Half of this clearing is planted with Liberian coffee, which could not be thriving better; the oldest trees are now eighteen months old and have fruit on them in all stages, and are in a perpetual state of blossoming, the wet weather not having the same effect on this coffee as in the case of the coffee Arabica.

The height of the oldest trees is over 7ft. 6in. I intend shortly topping them at 5ft. 6in.

It is the nature of this variety of coffee to bear very heavily when young, but it is for its future welfare not to allow it to do so, and accordingly to pick off the young cherries, but in the present case, when there is every chance of there being an early demand for seed, it would, perhaps, be found advisable to allow the trees to bear their utmost, keeping only a few trees separate for experiments and observations. On closely inspecting the coffee I find we have two, if not more, varieties, one kind sending its primaries out within a foot or so of the ground, while another kind often grows up to five feet before branching out. The former kind will, I am sure, be found the most serviceable, the higher trees, besides being top-heavy and apt to suffer from any night breeze, are also unhandy for picking and other works. It is at present too early to ascertain if there is any difference in the produce of these two varieties, but I shall ascertain as soon as possible.

The remaining half of this clearing is planted with cinnamon, Indian and Java coffee, nutmegs, cloves, pepper, citronella grass, sugar, (assorted) ginger, Ceylon cacao and aloes, all thriving as well as could be desired. Along the roads I have planted the African oil palm tree, which will in time give this clearing a very pretty appearance, while along the boundary the sapan hedge tree has been planted, which yields the valuable red dye, and has already commenced to seed.

In my last report I was able to write favorably of the young cinchonas, but since then they have nearly all died out, plainly showing that they are unsuitable for this low elevation. I shall, however, watch with interest the few remaining. All the cinchona vacancies have been planted up with cinnamon.

CLEARING No. 4, IN EXTENT 0A. 3R. 20P. is in the course of being planted with divi divi (which yields the valuable tanning materials)and gambier between the rows.

CLEARING No. 5, IN EXTENT 4A. 0R. 14P. is planted with ceara rubber and will, in the course of a day or so, be also planted with nutmegs.

CLEARING No. 6. IN EXTENT 14A. 2R. 26P.—This is nearly all planted with tea, (Assam Hybrid) the oldest planted being 14 months old and growing luxuriantly; the distance apart is 4×4, and so the clearing contains close on 30,000 plants, which will be sufficient for supplying seed, and also for experiments in tea manufacture.

On a small flat cotton trees have been planted, it being my intention to use them for growing pepper

* In Java Dadap, Erythrina.—ED.

vines up. Another small portion of this clearing has been planted with the croton oil plant, which, like all the other products, is growing well, and the same remark applies to the sago.

The nursery has now nearly done its duty, the only products remaining to be put out being cinchona ledgeriana and hybrid, para and landolphia rubbers, divi divi and nutmegs. There are, however, some surplus plants of Lib. coffee, tea, &c., which are being sold off; among the purchasers being, I am glad to say, some Chinamen.

EXPENDITURE.—It is to be expected in the case of opening up an estate in a new country, where experience has to be gained in nearly every branch, the work done will naturally be more expensive than in another country, and the Experimental Garden has been no exception to the rule. I have, however, gone carefully over the expenditure, deducting charges, such as superintendence, Wardian cases of plants, &c., which are rather unfair items to place against the garden.

The expenditure, therefore, for 1882 amounts to ...	$2,653·90
And expenditure for 1883	3,822·05
The total being therefore ...	$6,475·95

THE FUTURE UPKEEP I estimate at $150 per annum, which includes pay for a Mandore and a few coolies to keep the garden free from weeds, roads and drains clean, and sundry other necessary little works.

ESTIMATED VALUE OF GARDEN.

Cacao, 11 acres at $200	$2,200
Coffee (Arabica) 1 acre	100
Cardamoms, 1 acre	150
Lib. Coffee, 6 acres at $200 ...	1,200
Tea, 12 acres at $150	1,800
Miscellaneous Products	2,050
	$7,500

Above, I give an estimate of the approximate value of the garden, but it is, nevertheless, a very difficult matter to decide, there being so many points to take into consideration; for instance, in a new country like North Borneo, where all the necessary seeds and plants have to be imported, a garden such as this one would give a very handsome return from the sale of seeds, &c., for it stands to reason planters would prefer even paying a little extra to get plants and seeds fresh rather than import them at considerable risk and delay. Should it be the wish now of Government to hand over the garden to some planter at a suitable figure, I see no reason why they should not do so, for it does not much matter who owns the different products so long as they are *in the country*. As an investment it would, I feel sure be remunerative, it being the most advanced clearing in the country and would therefore have the monopoly in selling seeds and plants for some time to come, while its value to those proprietors who have large extents of land in this country to open and plant up would be immense.

Should, however, private enterprise not step in, I consider it is the duty of Government to keep up the garden. Even during the short time in which the garden has been opened, experience has already been gained, not only as regards the different products planted, but also the proper labour to employ, rainfall and other climatic influences which cannot fail to be of use to planters coming to this country. I am quite prepared to hear that, say for instance, Sugar is the product everyone is going to plant and what is the use of Liberian coffee, Cacao, &c.? Quite so. In many parts of Borneo sugar will, I have no doubt, be cultivated to advantage, but even in those parts the day may come, as has happened in Ceylon, when disease destroyed the staple product and there was then a general rush to the Botanical Gardens, whose judgment had been exercised in introducing a variety of different products, and planters were then able not only to judge as to suitability of the different products for their estates, but also to procure plants and seeds from trees in some cases twenty years old.

I was told one day that the garden at Silam was out of the way, and too far off for people to see: the speaker never made a greater blunder in his life, but in fairness I must say he had no pretensions to being a planter, for I maintain that no Experimental Garden in North Borneo can be too far out of the way for a man who comes to the country with the intention of investing his or other people's money. Speaking for myself, I know I should go direct there *before* selecting my land, duly noting any peculiar advantages it might have as regards soil, climate, &c. compared with other parts of the country and draw my own conclusions. The reasons Silam was selected as the site for the Experimental Garden are as follows:—

1st. On the score of economy the mountain being suitable for the growth of both high and low products and thus saving the expense of keeping up two distant establishments. Since then I have travelled over most of North Borneo and have not seen a more suitable place, though, I must say, I anticipated finding more high land suitable for hill products than I have done.

2nd. The soil in Darvel Bay was superior to that I had seen elsewhere and will yet be, possibly, the site of the first large plantation in North Borneo.

3rd. That Government had already started a station at Silam.

RAINFALL RETURN FOR SILAM.

TAVIUNI.

[FROM A CORRESPONDENT.]

I visited some of the coffee estates of Taviuni a short time ago. Delta (Mr. Phillpot's) is one of the best cultivated estates on the Island of Taviuni. The coffee trees are pruned to perfection, and the plantation is beautifully clear and free of weeds. There is a very good bridle path, two or three miles long, which goes from the main road to the estate. This has been made and is kept clear of weeds by Mr. Phillpot.

An immense amount of work has been done on the Alpha estate (Mr. Mason's). I found Mr. Stephens, the manager, deep in the mysteries of tea-curing. On the day of my visit a "flush" was being picked, and Mr. Stephens explained to me the process by which the leaves are converted into tea; but I will not venture to repeat it as I am certain I should make a blunder over it. The tea estate is looking well, and is well cultivated. The acreage under tea is being increased with all possible despatch. Mr. Mason intends to push the imported article out of the local market. When his new curing machinery, which has been ordered, arrives he will very much improve the quality of his tea, and will have no difficulty in supplying the whole of Fiji. At North Taviuni most of the planters not only use the Alpha tea, but prefer it to the imported article.

Forest Creek (Mr. Wilson's estate) was also visited. In passing through the various coffee fields I saw many of the trees loaded with berries, and I should judge a fair crop will be picked from the estate. Mr. Wilson has every convenience for pulping, drying and curing his coffee with all possible despatch. Mr. Wilson has cut and made a road, wide enough to take a horse and dray over, from his pulping house to his coffee curing establishment, a distance

of from three to four miles. This was a work of some difficulty and considerable expense. Rocks had to be blasted in several places, and three or four large and substantial bridges built before it was accomplished. I think I am correct in saying no other planter in Fiji has spent so much time, energy, and money in making a road outside his own estate. It was of course a necessary piece of work, but others participate in the advantages it confers as well as Mr. Wilson. When it was made there was jungle on either side; now the road is lined with native plantations.—*Fiji Times.*

CEYLON AND INDIAN TEA.

(From the *Indigo & Tea Planters' Gazette.*)

At the present time a deal of attention is being directed towards Ceylon and its production of tea, which, at any rate so far as regards quality, has during last season stood out in bold relief, and has caused our planters to gird up their loins for the struggle to come this year. The Brokers at home seem all pretty well to be of one mind, and that is, that Ceylon teas have excelled Assam, Cachar and Darjeeling growths of the past season, with one or two notable exceptions. There is no doubt that standard teas such as Budderpore, Borokai, Dooteriah and Kalej Valley, and others, are quite able to hold their own in the competition, and with something in hand, but how few are these amongst Indian teas compared to those quoted in Ceylon as attaining high values. With the information at present available it cannot satisfactorily be explained how this comes about. Can it be put down to climatic influences, or what? if so, it would appear that much land is available for tea culture which was before considered useless. We can scarcely think that our planters have lost their cunning in preparing the article, and we are inclined to think that locality has a good deal to do with it. Many years ago planters were wading in darkness with regard to manufacture, yet their teas invariably fetched high prices. Can it be that the Broker has been taken in by a new article, and that, after the newness has worn off, it will be discovered that Ceylon teas like Indian ones lose their keeping qualities in a few years? No, we cannot accept this explanation. Perhaps the one most difficult thing to explain is the reputed enormous yield per acre, combined with the fine quality. With regard to some of those companies quoted above, the only one which, as a public company, is referred to by our home contemporary, the *Home and Colonial Mail*, Borokai, is put down as consisting of 824 acres, which gives a yield of 199,200 lb., or about 3 mds. per acre; this is but a poor result as far as regards outturn, but looking at the dividend declared, it seems to bear uncommonly good fruits. In 1882 the result was 11 per cent, which considering the season, was highly satisfactory, and is best judged by its heading the list in dividends for that year as quoted on the London Exchange. Could Borokai produce at the same rate as the Ceylon gardens are said to do? We leave our readers to figure out what the result would be. Turn again to the labour question, and we find that Ceylon like Assam has to import its labor, but, although it does so, it would appear from all we can learn as if better arrangements were in vogue there than at present exist in Assam. In Ceylon the labor question is more nearly of a kin to the Dooars, and what is there known as the sirdaree system; and we believe that although the Ceylon planter pays perhaps a higher daily wage, having no bonus to pay, besides many other little comforts the Assam immigrant is supplied with, the result is at the end of the year cheaper working all round, and a contented labor force untrammelled with all the red-tapeism which is considered so necessary for a coolie the moment he leaves his *Mooluck* for the tea districts.

There are many other points with which we are unacquainted, that no doubt may tend to give a high yield in Ceylon, such as the rainfall and the close proximity to the sea. The latter no doubt is open to question as an advantage, but as a rule very heavy dews fall at night all along a coast line, so that if the rainfall is less when tea flourishes best, it may be that nature supplies the want in the excessively heavy dews. The temperature too is not to be lost sight of in taking everything into consideration, and being so near the equatorial line, the variation in temperature cannot be very great; which of course allows plucking to be carried on pretty nearly all the year round. Java teas have long been famed for their liquors, but somehow extension in cultivation there has not been rapid, nor would it, so far as one can learn, be attended with a large outturn per acre. Some years ago we saw tea in Java and the Straits Settlements flourishing fairly well, but we were by no means impressed with it as anything extraordinary in the way of outturn. The soil seemed much the same as what we understand the Sylhet Gardens mostly is, namely, a light sandy loam, very subject to wash unless carefully cultivated. The Maharajah of Johore, we believe, proposed going in for tea cultivation on a large scale, but as we have never heard of it as a success, we imagine it did not turn out the good thing it was expected. From the number of new names of estates in Ceylon that duly appear in the sale lists, it would appear as if there was now a pretty considerable area under tea in the island. At any rate, being in such an equable climate, we must not forget in comparing the results of the sales, that the Ceylon teas that met our Indian produce in July and August are the Ceylon second or third flush meeting the first flush from India. That this is an important factor no one will deny, and we will perhaps in a year or two, when many private concerns are converted into limited companies, be better able to judge from the share lists whether the result at the end of the year is so widely different from our Indian estates, as rumour would at present have us believe. One thing the Ceylon planter seems to beat our Indian planter in, and that is in putting his wares before the purchaser. From remote corners in New Zealand we have lately heard that Ceylon teas are to displace Indian, and that we have a formidable rival now in addition to China. Well done Ceylon, nothing like it, the colonies are somewhat like America, and are to be done best by advertizing, and the Ceylon planter seems to have found it out, and that too quickly. Able to hold their own in outturn and prices, what more is left? We advise our Indian friends to be on the *qui vive.*

THE CHINA TEA TRADE.

In regard to the trade in black teas for 1883 the *China Mail* remarks:—

The dangers that beset the trade and threaten its future are set forth with convincing force in the Foochow Report, and it is earnestly to be hoped that such warnings will be heeded. The total export of black tea represents a falling off of 2½ per cent from the export of the year before. The decline has been continuous since 1880.

In regard to green teas, on the other hand, although exports have diminished, prices are represented as having been good:—

Green Tea.—The Green Tea season 1883-84 has been a very good one indeed for native teamen as well as for foreign shippers. This unusual and most welcome experience is attributable to the smallness of the quantity exported to the United States—the chief consuming country for this staple—and to the consequent rise in price there, which took place in the latter part of the year 1883. Early in that year the Act against the importation of tea unfit for human food went into operation in the United States, with the effect of reducing very considerably the export of common teas from China to that country. The smallness of the export has also been due in part to the difficulty which—owing to the financial distrust prevailing early in the year—the teamen encountered in their efforts to obtain advances. The export of green tea to Great Britain has been slightly larger—say, some 700,000 lb.—than in the season previous; but the export to the United States is only about 11,500,000 lb., as against 18,000,000 lbs. for the season before. The rise in values during 1883 has been very marked; the quotation for fine Moyune and Teenkai chops in New York in January was 23 to 24 cents, and in December

for similar teas, 29 to 30 cents. In London also the aise may be estimated at fully 10 to 15 per cent on fine and 20 to 25 per cent on common teas. The year has been remarkable in the American green tea market for the courage shown by many importers in 1883 in holding on to their stocks through periods of slack demand,—a course which has strengthened confidence, and tended to check the disposition natural in dull times to force off Teas at public auction. In point of fact, the quantity green tea sold in the latter half of 1883 in New York in the manner referred to represents but 50 per cent of the quantity thus disposed of in the year before.

In describing the opening of the Tea market at Hankow, the *Shanghai Courier*:—

The quality of the crop is decidedly superior to that of last year, the weather having proved everything to be desired: heavy snow in February and almost continuous sunshine since: nothing is lacking but care in the manipulation, which the Chinamen have apparently made up their minds it is no longer worth their while to expend, the demand being, with few exceptions, for price entirely.

THE COLLAPSE OF THE BRAZIL AND HAVRE SYNDICATE and its results are thus noticed in the *Rio News*, the editor of which paper, it will be observed, estimates the loss of the ring at over a million sterling:—The misguided enterprise of the syndicates and their friends in buying coffee on the Havre market for a rise, has resulted in a heavy loss. This might have been expected. Without accurate and full knowledge of the world's production and consumption, and without even a definite knowledge of the crop prospects of Brazil, these gentlemen were certainly very poorly equipped to undertake a "bull" speculation on the Havre and New York exchanges. They had the conceit, however; and now they have less conceit, less money and more experience. According to an evening contemporary they have lost 20,000 contos, while the broker's estimates vary from £1,000,000 to £1,250,000 sterling. This is equivalent to a loss on the latter estimates and in round numbers, of from 470,000 to 580,000, bags of coffee, or nearly a tenth of the whole crop of the country. Experience, it should be understood, is a very expensive teacher. We need not say that Brazil is in no position to lose such a sum of money just at this time, but if the loss serves to teach her planters and factors to mind their own particular business—the production and marketing of the product—it may not have been lost in vain. It is pure folly to suppose that local syndicates can either control the markets of the world, or execute a successful "bull" operation on foreign exchanges. They have neither the capital, knowledge, or experience. The sooner the planters and their factors master the fact that Brazil is only one among many producing countries and that they cannot influence the prices in consuming markets by any local combination, the sooner will they get rid of all this sentimental nonsense about foreign speculators and foreign combinations. The consumer is bound to buy at the lowest price obtainable. If overproduction and competition force down prices below the cost of production, then the planter must either cheapen production or turn his attention to some other industry. Of one thing he can rest assured: the old margins of profit on coffee production are over and are likely never to return, except it be in some year of general short crops. If he intends to continue growing coffee, he has one course open before him: cheaper and better systems of cultivation and preparation, and cheaper and better facilities for putting his product on the market.

CACAO CULTURE IN THE EASTERN PROVINCE OF CEYLON.—Land can be procured in any quantity at the upset price of R10 per acre, and, as regards Mr. Fielder's successful experiment, we learn that the seed from which his clearing was planted, came all from Pallakellie. Planted under shade, he found the trees to succeed the best; labour employed coast coolies. The trees from which the pods we noticed recently were picked have *had no artificial irrigation whatever.*

GROUND NUT TRADE.—We hear that the ground nut trade in Pondicherry, is likely to be much larger this year than last. Many ships and steamers have been fully freighted with ground nuts from Pondicherry, and many others have been chartered to load nuts at that port for France. Supplies from the interior of the South Arcot district continue to arrive in abundance, and while the trade of the settlement is being pushed on, the South Indian Company continue to run special trains with nuts between Punrooty and Pondicherry every day, and are likely to do so for the next three or four months.—*Madras Standard.*

COCONUT OIL is said to be a cure for scorpion stings. A correspondent writes to a Bombay paper:—"I was at one time stung by a scorpion in the palm of the hand, and a native of Singapore, where I was at the time, being present, recommended its application as a certain cure. I followed the advice given, but in the mean time sent for the ordinary remedy ammonia This latter I had no occasion to use, as in less than two hours the whole of the swelling, which was very great, had disappeared. The only other inconvenience was a slight irritation for about six hours. The coconut oil was well rubbed in almost immediately after I was stung."—*Madras Mail.*

THE COFFEE MARKET.—In the Wynaad and in Coorg, as well as in Travancore and Ceylon, the position and prospects of coffee are regarded with profound apprehension by a class of enterprising patient men towards whom Nature has been anything but indulgent for several years. Twenty years ago the middle-aged capitalist who went into coffee as the buyer of young estates, or the opener out of new ground, was regarded as a man who was doing an uncommonly good thing. But now capitalists wont look at coffee. Twenty years ago youths in the Army readily exchanged their swords for pruning knives, and fondly calculated on succeeding after ten or twelve years of a "good time," in doing sufficiently well to enable them to retire with a competency to their native land. But now recruits of this class may be looked for in vain in the coffee field of labour. A great change has come over the whole industry, and has filled with foreboding the minds of those who have succeeded in hanging on to coffee in the fond hope of a turn in the tide of misfortune. To these persons especially the statistics relating to coffee are of intense interest. Unfortunately the figures are not yet encouraging. On the 1st ultimo, the stock of coffee in Europe was 217,100 tons, as compared with 160,250 tons, on the corresponding date in 1883, 164,800 tons in 1882, 143,850 tons in 1881, 114,050 tons in 1880, and 95,400 tons in 1879. So the stock on the 1st ultimo was more than double the quantity held on 1st April 1879. The stock has accumulated so much this year, that, as a natural consequence, prices in all markets have fallen very considerably. But the outlook for cultivators is not quite so bad as one might be led to suppose by the foregoing figures.—*Madras Mail.*

THE TEA ENTERPRIZE.

Below we give many matters exclusively connected with the manufacture of tea, the extracts being mainly from a very valuable series of articles on tea machinery which has appeared in successive issues of the *Indigo and Tea Planters' Gazette*. Our readers cannot help sharing our feeling that the perfection to which tea machinery was brought by the time the enterprize in Ceylon had passed from the experimental stage, has placed our planters in a very advantageous position and under a great obligation to the Indian tea-planters who, during a period of from forty to fifty years, have been working out results, of which we have the benefit, by a series of painful and expensive experiments. The old superstition in favour of the primitive choolas and the troublesome, expensive and, in close factories, dangerous charcoal-heat has been finally dispelled, and by means of Davidson's siroccos teas can be dried to perfection, not merely by means of ordinary firewood, but by burning grass where firewood is not available. We owe so much to India, in truth, that we almost feel inclined to apologize to its planters for the lead which our teas have taken in the market. We quote an article from the paper already referred to in which a solution of the problem of our success is desiderated. Much of that success is due to what Mr. Baker and other early visiters to our island regarded as great drawbacks: our wet climate and the absence of a distinctive winter. Ceylon is an island in the track of both monsoons, and is 20° nearer the equator than most of the India tea districts. The result is a much more genial climate, with a rainfall varying from 70 to 250 inches in the south-western and mountainous portions of the colony. In India, there is also a rainfall of 70 to 250 inches, but the bulk of it falls in from four to six months, while long continued droughts and hail-storms are frequent, and all growth is arrested from November to March by a decided winter. Here in Ceylon, November and the first half of December are periods of heavy rain, and, although our fine season on the hills extends from the middle of December to the middle of April, yet there is rarely or never a month without rain, and growth is not arrested. In Ceylon, therefore plucking and preparation might practically go on all the year round, but that prudence dictates a rest by means of pruning. But such is the forcing nature of our climate, as regards leaf, that the bushes are scarcely pruned when they commence flushing freely again. The effect of our insular position, contiguity to the equator and genial climate is that an altitude of over 5,000 feet here is only the equivalent of 3,000 feet and under in Darjeeling. The consequence is a large yield of leaf, not only in the hot steamy lowlands, but to the equal surprise and pleasure of proprietors of elevated estates, at altitudes of 4,000 to 6,000 feet. We believe we are within the mark when we estimate an average of 700 lb. per acre for the lowcountry estates, 600 lb. for medium elevations and 500 for the high estates, 5,000 feet and over. This is, we are bound to confess, more a matter of climate than of soil, although the soil in many places, especially at high elevations has been declared by visitors from the Indian tea districts to be excellent. It may not be so deep and so rich as that of the valley of the Brahmaputra, the Himmalayan slopes, the Terrai and the Dooars, but it has good staying qualities able to support vegetation and to resist wash and sun-combustion. Of course time and repeated cropping will tell everywhere, but probably more rapidly in the lowcountry than in the high; but when the period for manuring comes, Ceylon is favourably situated in the proximity of the estates to the seaport and the existence of good means of communication, railways as well as roads. It is true that in money wages we pay more to our labourers in Ceylon than is the case in India, but we have no bonuses and no expensive system of recruiting. The stream of labour from Southern India goes and comes freely, and as a general rule supply is more in proportion to demand here than is the case in India itself. Our advantages therefore are many, and, judging the future by the past, our planters will make the most of them, so as to retrieve by means of tea the fortunes of the island enterprize temporarily wrecked by the effects of the coffee-fungus and of over production in Brazil. But, while naturally pleased to find our circumstances so good and our prospects so hopeful, we can only wish continued good fortune,—or rather a return of it, to our Indian brethren. The fact that 6,600,000 of India tea were taken for consumption last month in Britain is certainly an encouraging sign.

JACKSON'S TRAYLESS TEA DRIER.

We find the following description in the London letter of the *Indigo and Tea Planters' Gazette*. The new machine seems to embody some of the principles of the Clerihew. It will, of course, require water or steam power to drive the fans.

On Wednesday, a party consisting of the following gentlemen, well-known to all connected with tea planting, by reputation if not otherwise, *viz.*:—Messrs. C. Hudson, E. Wahab, A. B. Inglis, Cooke, R. B. Magor, Sefton (L. M. B. Manager) Peet (of Messrs. Peet Bros., Java Merchants), went down by early train to Gainsborough to inspect Mr. W. Jackson's new Tea Drier. On arriving they were received by the Patentee and driven to the splendid works of Messrs. Marshall Sons & Co., where they were warmly welcomed by the very courteous members of the firm, and conducted through the huge establishment: passing boilers, engines, and machines, innumerable, many of which were of sufficient interest in themselves to justify the journey from town, notably the brick-making. The Messrs Marshall make their own bricks, and here one sees what applied science can do in the way of saving labour and "lifting." The unbaked bricks are placed on trucks, the trucks pass on rails into the kiln, remain in the kiln, the necessary time with the bricks on them and then emerge with their loads of baked bricks, other trucks at once taking their place. Thus there is no lifting of the bricks or building and unbuilding of the kiln. But, though sorely tempted to describe many other of the interesting and most valuable contrivances passed in the traversing, I had almost said the miles of machine shops in the establishment, for they appeared interminable, ere reaching the Drier that was the special object of attraction on this occasion—I must refrain, or I shall have no space left for the Drier itself. On reaching the Drier the party were at once struck with its suitability, its internal arrangements were found to be on an entirely different principle from any former one, and it is certainly superior to that of Kinmond's or any other Drier. In Kinmond's the trays are objected to by many, whereas in this new Drier the trays are totally abandoned and endless bands are substituted, as they have been already in Mr. Nelson's machine (of Dehra Dun). In Mr. Nelson's machine the bands were contained in a long case, in this machine in place of the long case, with only two bands one above the other, there are several bands in a more conveniently shaped case. The hot air supplied by a furnace below and heated pipes is sucked up and expelled from the top by a suction fan, not blown through by a fan as in Mr. Nelson's, thus reserving the latter's method. The rolled tea is placed in hopper on the top of the machine not far from the fan. The tea then falls upon the uppermost endless band. This band, like its fellows, consists of metal plates and revolves on drums, carrying the tea forward with it, and dropping it into the band next below it, which being longer than the top one, receives the tea, and takes it back in the op-

posite direction, dropping it in turn at its other end upon a lower and longer band working in the opposite direction to the one above it, which latter again takes it back and drops it on a third lower and longer band, and so on till the lowest is reached, when it emerges from the machine completely dried. To prevent the tea from collecting in lumps when thrown into the hopper, in other words in order to sprinkle the tea and well and evenly over the surface of the upper band, a patent "Kicker," is attached. By pushing against the tea in its effort to be carried along by the band, the "Kicker" has the desired effect, and Mr. Jackson attaches very considerable importance to this feature in his Drier. Thermometers can be attached showing the heat at different points, and as both the speed at which the bands revolve and the heat can be regulated and are under perfect control, there is only the danger of carelessness to fear, so far as burning goes. An experiment was tried with elder leaves. These were rolled in one of Mr. Jackson's "Excelsiors" then saturated with water, so, that on squeezing a handful the water poured out. In 15 minutes after being thrown into the hopper they emerged perfectly crisped and dried and without sign of burning. Elder leaves are not tea leaves it is true, but the result was eminently promising. The patentee has formed his calculations as to its working capacity, but does not wish to publish them until he has put them to the proof after the machine has been tried with tea. The price has not yet been decided upon. This Drier is going out to Cinnomara, one of the Jorehaut Co.'s gardens, on trial. The party of inspection appeared of one opinion, *viz.*, that only one thing prevented a decided expression of thorough approval and confident, and that was, that tea leaves are possibly not to be judged by the behaviour of elder leaves. PERIPATETIC PLANTER.

TEA MACHINERY—ROLLING MACHINERY.

(From the *Indigo and Tea Planters' Gazette.*)

No person is more indebted to the aid of machinery than the tea planter, especially in the process of rolling. It is by no means unusual in the height of the season to see 5,000 lb. of leaf plucked in a day in a medium sized tea garden; and when it is considered that a man's daily task at hand-rolling is to roll about 40 lb., and that thus the above quantity would therefore require the daily labour of over 120 men, whereas it could be easily rolled in less time by an Excelsior or other well constructed rolling machine, the value of the application of machinery to the process will be perceived: indeed it is difficult to conceive how, with the present scarcity of labour, the tea manufacture in India could be carried out to the extent it is without the aid of machinery. As the rolling machine is the most important aid to the tea planter, we will give it the first place in the present series of papers describing the machinery used in tea manufacture. And let me premise my remarks by reminding the reader that it is always difficult for an engineer to describe machinery without resorting to technical words and phrases not easily understood by persons not members of his own profession. In these papers such technicalities will be avoided as much as possible. The question naturally arises at the outset as to why tea should be rolled. There are two good and sufficient reasons for this. The first, is that it is necessary to break the cells of the leaf in order that the juice or sap may be exposed to the oxygenating effects of the atmosphere during that most important stage of tea manufacture desiguated for want of a better term the "fermentation" of the leaf. The second reason has reference to the after processes of sifting and separating the tea after being dried, as the closer and more compact the twist given in the rolling machine, the greater will be the quantity of tea which will pass through the meshes of the sifting machinery, and consequently there will be a less percentage of coarse tea, and thus less necessity for breaking the coarser tea and the consequent distinction of their appearance and production of dust. Each process in tea manufacture is so intimately connected with the others that success in all can only be obtained by a close attention to each; thus the success in rolling depends much on the care and attention paid to the withering process, an even fermentation will only be obtained when the leaf has been evenly and coolly rolled, and so on. As to the extent to which leaf should be rolled opinions differ. I know a concern in which the superintendent, one of the best tea makers in India, insists on rolling the leaf up to a point at which, according to ordinary opinions, the leaf is utterly destroyed. Most persons content themselves, however, with giving the leaf as good a twist as they can without breaking it up. We will next proceed to consider the essentials of a good tea rolling machine before proceeding to describe the different machines themselves. The first great essential is a large outturn. In the height of the season, except in a small factory, the rolling machine should be able to turn out daily a minimum of well-twisted leaf of about 60 maunds, or say 4,800 lb., and this even when the leaf is hard through cold weather or excessive rain. The rolling should be done in a period of time not exceeding ten hours, so as not to have the fermenting and drying process going on after dark. Everyone who has had any practical experience of the working of a tea factory knows how important this is. The tea makers get tired, and are apt to be careless in a process which requires the most unremitting care and attention. It is also difficult to see the correct colour of the fermenting leaf by lamplight. Every tea house therefore should possess sufficient rolling and drying power to finish off every thing, even in the height of the season, or when the leaf is difficult to wither, by 5 p. m. The importance therefore of having a machine capable of turning out quickly large quantities of leaf is obvious. There is another reason of great importance. The leaf must not be over-withered before being rolled, and as sometimes a lot of leaf is ready at once for rolling, it is important that it should be manipulated as quickly as possible before it gets too much withered. The second essential in a good rolling machine is, that it must give a good twist to the leaf without breaking or crumbling it up much. I referred above to the advantage to be derived in the sorting stage by the leaf having been previously well twisted, but this is not the only one arising from a good even twist. The more evenly the tea is twisted, the more regular and even will be the fermentation, and consequently the liquor and outturn will be better, and the tea fetch a higher price. It is most disappointing to a good tea-maker to have all his efforts in the tea-house nullified by his rolling machine being unfit to give a good even and firm roll to the leaf. It is essential, or at least in the opinion of most tea-makers beneficial, that the leaf should be rolled as coolly as possible, and that as little heat as possible be evolved by friction in the process. The lower the temperature of the leaf is kept during the process of rolling the better and more even will be the fermentation. Another important point to be noted is, that no iron in the machine should come in contact with the tea, as iron tannate, a substance similar to writing ink, would at once be formed and the tea discoloured. Another point of very great importance is that the machine should be capable of being readily filled and emptied. When leaf is spoiling in the withering loft by being overwithered, or when heavy flushes are on the garden, and much leaf coming in and every minute is precious, the importance of the above cannot be overestimated.

The last and one of the most important of the essentials of a good rolling machine is that it should be of simple construction, not liable to readily get out of order, easily repaired and kept in order, and easily driven. Few concerns can afford to keep an engineer or mechanic of their own, and it is not always easy, especially in the rains, to obtain the services of a competent man; nor do most planters care about taking on themselves the responsibility or trouble of repairing their own machinery, even if competent to do so, which few are. Moreover it is a great loss to have to take a lot of men from the hoe to roll the leaf, just when they are most needed at their legitimate cultivating work. It is then extremely desirable that tea machinery, and most of all the rolling machine should be strongly and simply constructed so as to minimize the chances of a break-down.

Let us now proceed to consider the different machines used in rolling tea leaf. It is difficult to obtain the facts as to whom the credit of introducing machinery for rolling leaf must be given, but I believe Mr. Nelson to have been amongst the first if not the first inventor in this line. I will proceed as much as possible chronologically in describing the machinery so that the reader while studying its construction may also observe the various improvements which have taken place, and its gradual development.

In the first place I must state tea rolliog machines are divided into two classes: 1st, those in which the leaf is placed in hags to be rolled, and 2nd, those in which no bag is used. Mr. Nelson's machine, which I will now proceed te describe, belongs to the first of these classes. [Then comes a description of Mr. Nelson's machine, which we omit, as of no practical interest te tea-makers in Ceylon. —ED.]

Mr. Kinmend next followed suit with his first rolling machine, which in its time did good and valuable work. [This also, being superseded, we omit.—ED.]

Mr. Jackson next appeared on the scene with his well-known "Single Action" Rolling machine. This invention was designed to imitate the action of a coolie's hand when rolling leaf, and the inventor was most successful in doing so. The introduction of this machine led to considerable litigation between the inventor and Mr. Kinmond, the latter claiming that as Mr. Jackson rolled his leaf upon a table, that table being used to give an upward pressure to the leaf, he infringed Mr. Kinmond's patent. The case was eventually decided in Mr. Kinmond's favour. There can be no doubt, however, that Mr. Jackson's motive in this invention was to imitate the motion of the human hand as used by the cooly when hand-rolling, and that this motion is very different from that given by any of Mr. Kinmond's machines. And that Mr. Jackson was right in his idea is proved by the fact that the machine is a good deal used, yet, although the inventor has brought out other very superior machinery, it is claimed for it by some of the most experienced planters that it is better adapted than any other machine for very hard leaf, or where the leaf has to be twisted more than is usually done, as some planters believe in doing. The machine consists of a square frame-work, inside of which there is a flat table hinged at one end to a projecting part of the frame-work and suspended at the front of the machine by chains passing over grooved pulleys attached to the frame-work. These chains carry a number of weights, by which the amount of pressure on the leaf can be regulated. In the bottom of the table there is a trap door easily opened and shut, by which the leaf can be allowed to escape from the machine without stopping it. The leaf is enclosed and prevented from escaping by a square box strongly constructed of iron, lined with wood inside to prevent contact between the leaf and the iron, for reasons given above. The upper part of the rolling portion of the machine consists of a heavy block of wood about 30 inches square and about 15 inches high, square in shape, and the inside well hollowed out to represent as much as possible the hollow of the human hand. The hollow is deeply grooved in order to assist in turning the leaf. By an ingenious arrangement of double machinery gearing the box containing the leaf is pushed horizontally in two directions at right-angles to each other, and the toothed wheels in the driving gear are so arranged that the motion is given twice in one direction for once in the other. The leaf is thus driven about on the table in a form something like the figure 8, and thus being well turned over the leaf cells are quickly broken and a good twist given. On the top of the wooden block there is a hopper through which the leaf is fed. The wooden block itself, which forms the most important part of the machine, is suspended from the top of the machine, by four iron rods, working at top and bottom in what are known as ball and socket joints, allowing the block, the representative of the human hand, to move freely in all directions. The peculiar motion given to the ball of leaf by this machine, renders it very effective for hard leaf. I think the Lyle machine comes next in order of time. It is said that the original idea of this machine originated with Mr. Haworth, another inventor, and that he abandoned it for his present machine. Be that as it may, the machine displays considerable ingenuity, and, although a bag machine, it possesses considerable merit, and is certainly the best of the bag machines. * * * * With the Lyle machine I think we can drop the older classes of rolling machines, and consider next the series of newer inventions, beginning with Mr. Kinmond's improved rolling machine and going on until the series of inventions culminates in the latest and most admirable invention of Mr. Jackson's in rolling tea leaf, the Excelsior rolling machine. The following machines will be treated of:—Kinmond's improved ; Haworth's a bag machine; Jackson's Cross Action ; Kinmond's Centrifugal ; Jackson's Rotary ; Thempsou's Challeuge, and Jackson's Universal and Excelsior machines. A few short remarks will be given on the methods of putting down the machines.

TEA MACHINERY—DRYING APPARATUS.

(From the *Indigo and Tea Planters' Gazette.*)

Before entering on the very important subject which gives the title of the present chapter, I wish to make a few practical remarks on the laying down of tea machinery : and as these remarks apply to all classes of machines used in tea manufacture, I may remark generally that a good deal of the successful working of a machine depends upon the care and attention bestowed upon the construction of the foundation. In my own practice I invariably make the foundations extremely strong, and am happy to say that my results have proved the wisdom of this course. Tea machines are bolted down to heavy timber beams. I will describe as carefully and simply as possible my own method of laying down the foundation for the Excelsior Machine, and from this the planter may be able to make and apply rules for the successful setting down of any machine.

I use for this machine two longitudinal beams, measuring 16 feet in length by inches 14 square. I dig a pit in the ground about 16 inches deep, 18 feet long, and sufficiently broad to leave about a foot clear on each side of the beams. In the bottom of this pit I lay a bed of concrete consisting of either broken brick or stone rubble, with lime and seorkey, sand and Portland cement or any other good concrete. The pit must be deep enough, and the layer of concrete sufficiently thick that the top edge of the beams will be about 2½ inches above the surface of the tea-house floor. This is in order that the floor can be sloped away for a distance of about three feet on each side of the machine ; the *feet* of the machine being thus raised higher than the level of the floor. This is a great advantage in sweeping dust or dirt away from the machine. There is a truck or bogy provided for conveying away the leaf from the Excelsior. It is advantageous to have a pit between the two longitudinal beams sufficiently deep to allow this truck to be below the level of the ground when wheeled into the pit. The pit will thus be about 9 inches deep from the top of the beams, and a slope or "ramp," to use the engineering term, must be constructed to allow the truck to be conveniently run up and down into the pit. A cross-piece should be inserted connecting the two longitudinal beams near the end at which the driving gear is, and this should be dovetailed into the side beams, so as to prevent side vibration. If this cross-piece be well fitted and the concrete carefully rammed down round the foundation beams, the machine will work without vibration and without the consequent risk of breakdown. Care must be taken that the feet of the machine are quite level, the tops of the beams being carefully pared away to admit of this. The machine should not be worked for some days after being laid down, or else, as can be easily done, the foundation ought to be ready to receive the machine before the latter arrived, so that the concrete foundation may be properly set. Before leaving the subject of rolling machinery and going into the very important one of tea drying machines and apparatus, I may mention that the Messrs. Jackson are bringing out a small drying machine to be worked by hand-power and suitable for the smallest gardens. The cost I understand is to be very low, so as to bring it within the reach of everyone.

We will now pass on to the subject of tea drying apparatus. After the leaf has been removed from the rolling machine it is allowed to "ferment." This term is used to express the oxygenating process to which the leaf must be exposed, and is only an empirical expression, as the chemical process through which the leaf passes is not in the least akin to fermentation. As soon as the leaf becomes sufficiently oxygenated it is dried off as quickly as possible. It is a disputed point amongst tea makers, as to whether or not this drying or firing process should be done by means of charcoal, or the more recent methods of hot air drying. Many persons still believe that drying the tea by charcoal has the effect of giving it a better "keeping" effect ; there being no doubt that the least exposure of tea to the air after being packed, does, to a great extent, deteriorate it. Ebis, however, is not the place to discuss

a question of this sort. There are many stringent objections to the use of charcoal in tea drying. The crude apparatus used in which one can never be certain that his tea is not burned, (except when the old-fashioned "dhool" is used, as it is by some noted tea-makers to this day,) the great cost and trouble of making charcoal, the growing scarcity of wood in the tea districts, and the great space taken up by the charcoal drying *choolas*, thus necessitating large tea-houses, have long led the minds of practical tea-planters into desiring a quicker and cheaper method of drying tea than by the charcoal *choola*. And I think the credit must be given to the Messrs. Jacksons for the first attempt, not a great success, however, on their part at that time, to dry tea by means of hot air. It is strange that the Jacksons, certainly the most successful inventors of rolling machines, have been so unsuccessful in bringing out a successful tea drier. I am glad to say, however, that the latest Jackson drying machine promises fairly to beat anything in the market. The new machine has not been tried yet, but the foundations are being erected for it at Cinnamara, and before the end of the present season it will have been thoroughly tested. The first successful machine was brought out by Mr. S. Davidson of Belfast. I mean the well-known "Sirocco." There have been several changes and improvements in this apparatus since it was first introduced, but all along the same principles have been studied, and as far as quality of outturn is concerned with the most undoubted success. Like all hot air machines it consists of two parts: first the furnace in which the air is heated; and second the part of the apparatus in which the tea is exposed to the action of the hot air. The heating part consists of a series of perpendicular rectangular chambers, divided by thin sheets of disphragms of wrought-iron, the frames holding the sheets themselves being of cast-iron. These are so arranged that a current of air passes upward from the external atmosphere to the tea drying portion of the apparatus, through every alternate cell or chamber hot smoke and gasses from a furnace in the centre passing down through the adjoining chambers. The heat from the adjoining smoke cells passes through the thin sheet of iron separating them from the air cells, and is taken up by the air: it being so arranged that the hottest air in ascending, meets the hottesr smoke in descending, so as to take as much heat from the smoke as possible. The air, after being thus heated, goes on through a series of four trays on which the leaf is spread. The leaf is first spread on the topmost tray, and as soon as the leaf on the bottom tray becomes properly dried, the tray with its quantum of leaf is removed, and the other trays are brought a place lower down. The process is repeated as each bottom trayful of leaf is properly dried, and so on *ad infinitum*. It will be seen that the nearly dry tea in the bottom tray gets the driest and hottest air, for if the air were not well dried and hot it would fail to extract the last particles of moisture from the tea, and render it liable to mould or become musty. The hot air after having done its duty as far as the tea is concerned passes into a chimney, where being joined by the smoke, it helps to cause the upward draft necessary to draw it through the heating cells and tea, as in this machine no fan is used. The teas turned out by the Sirocco are noted for their fine flavour. They acquire a crisp, malty, brisk flavour much prized in the market. The only objection to the Sirocco is, that one machine only turns out at the very outside about 40 lb. of tea per hour, and then under very exceptional circumstances. I see by a recent number of the *Indigo and Tea Planters Gazette* that the proprietors of the Sirocco suggest giving all teas fired in other machines a final fire in the Sirocco in London, and promise an improvement in flavour and a consequent increase in price. The experiment is well worth trying. It is to be regretted that the outturn of the Sirocco is not greater.

Mr. Kinmond about the same time appeared on the scene with his well-known tea-drier. The first machine, like the first of his rolling machines, was a crude attempt and not very successful, but has been greatly improved upon by the inventor. The principle chiefly relied upon by the inventor in this machine is that the air once used to dry the leaf is re-heated and used over and over again, being supplemented by a small portion of fresh air continuously admitted. On the face of it, this supposition is a fallacy, as it must be quite apparent that a certain number of units of weight of air must be admitted to the machine to carry off a certain weight of water, provided that the air be admitted at a constant temperature and released at a constant higher temperature. Any advantage which may be claimed by Mr. Kinmond in his machine is in the quantity of tea it turns out. Many tea-makers find fault with it on account of the very reason, which the inventor considers an advantage, namely, that the same air is used over and over again. This air is necessarily heavily charged with moisture and less able to take the moisture from the leaf. Planters object to having their tea dried by a mixture of hot air and aqueous vapour, no matter how highly heated. Another objection to the machine is that, the air being forced through by a fan, a lot of the *dhool ghoorie*, or fine tea is blown about. This, however, can easily be attended to. The great quantity of dry tea turned out of the machine, must be an argument to some extent in its favour, and I think if the old idea were given up that the same air should be passed over and over again through the machine, a better flavoured tea would be turned out. Or this drier might be used with advantage in combination with another machine, the Sirocco for instance, the latter being used to finish the tea partially dried in the Kinmond drier—or the tea might be finished over charcoal.

This machine is made in three sizes, to dry respectively one, two and three maunds of *pucka* tea per hour. The No. 2 size is the one mostly used. They are alike in construction and principle, and only differ in size. A furnace below the machine gives the necessary heat to a current of air passing over an iron plate which forms the roof of the furnace and smoke flue. In an iron-casing standing above the furnace there are no less than 18 drying trays and others besides to catch the *dhool ghoorie*. One peculiarity, and a very commendable one, in the machine is, that each tray has a separate current of air to itself. The current of air, heated by passing over the hot flue, is driven by a fan through the trays on which the tea is spread, and after passing through them is again sucked in to the fan forced by it over the hot flue and on again through the tea.

This machine is much used in Assam, and is highly spoken of by many persons who use it. Others again condemn it for the reasons above-stated. It is very substantially and neatly constructed, (as indeed is also its rival, the Sirocco), and is far ahead of any other tea-drier in the quantity of its outturn.

JACKSON'S NEW TEA DRYING MACHINE

from which so much is expected, is thus noticed by the writer on tea machinery in the *Indigo and Tea Planters' Gazette*.

As mentioned above, however, the Messrs. Jackson are bringing out from England a new patent drier of their invention, which is shortly to be erected in Assam; and having seen the drawings of it, I am able to describe it. It is to be erected at the Cinnamara Tea Estate, Jorhat, and the foundations are now being laid down for it. It is to be a continuous feeding and discharging machine.

A furnace at one end of the sub-structure of the machine communicates with a horizontal smoke flue running rather more than the whole length under the drying portion. In this smoke flue there are four rows of cast-iron pipes running horizontally and having their ends curved up into the air drying chamber. These pipes communicate at the other end with the outer air and a constant current of air is drawn through them and exposed to the heating action of the hot furnace gases in the smoke flue. The roof of this flue is a corrugated plate of cast-iron, the corrugations being given for the purpose of strength, and the plate is still further strengthened by deep narrow bars being cast on its upper side. The flue is furnished with iron doors on the side for the purpose of cleaning it, and on the end opposite the furnace sits the chimney. Upon this flue rests the hot air chamber in which the drying of the tea is effected. This consists of an iron chamber oblong in its horizontal section, but gradually narrowing towards the top lengthways, one of the ends being sloped. Within this drying chamber there are five travelling webs of wire gauze on which the tea is dried. By a peculiar apparatus the tea is shaken on to the end of the top web, and by the

shaking motion is evenly distributed upon it. The tea is then carried along on the web, which revolves on rollers at each end, and as the webs turn over the roller it drops the tea on to the next web, which is somewhat longer than the first. It then travels back on this one in the opposite direction, and at the end falls in the same way on to web No. 3, which is also, as they all are, longer than the one above it. This is repeated on two more webs, the tea meeting the current of hot air the whole time, until it finally falls out of the machine into a receptacle from the end of the fifth or lowest web. The air is not forced through the heating tubes and drying chamber as in the Kinmond Machine, but drawn through by an exhaust fan on the top of the machine. As the air would be too hot for tea at its entrance to the drying chamber, there is provided a door opening to the external air near the inner months of the pipes, by means of which a certain quantity of cold air is allowed to mingle with the heated air and bring it down to a proper temperature, and this is shown by thermometers placed near this door. The hot-air is allowed to impinge on the drying tea in two places, first at the end of the bottom web, and next at the end of the second web from the top. Thermometers are placed in several parts of the machine to show the temperatures at the different stages of drying. The speed of the travelling webs can be increased or diminished as required by means of cone pulleys. There are the necessary openings for removing the *ghoorie* or fine tea that falls through the tray, and angle iron guides are fastened along the inside of the chamber to prevent the tea from falling off the webs. The tea will be fed into the *shaker* or distributor by a boy, and will require no attention until it is discharged from the last web, except seeing that the temperature of the drying air be properly regulated. The reader will observe also that the tea in falling from the end of each web on to the next one *turns itself*, a point of great value.

This machine will, I have no doubt, prove a great success, as it fulfils, as far as I can see, every essential of a good tea-drier. The tea is dried by pure hot air, the temperature of which in any part of the machine can be regulated. It will require little attendance. A boy to feed, another to remove the dried tea, and a man to fire and watch the temperature of the air, will be all the attendants needed. It is bound to be economical in its consumption of fuel as no more hot air will be used than necessary, and as the flues and drying chamber will be surrounded by non-conducting material, the loss of heat by radiation will be reduced to a minimum; and being of large size it will be capable of turning out a large amount of *pucca* tea. This apparatus should combine the advantages possessed by the Sirocco and Kinmond machines without the disadvantages of having to use trays and consequently to increase attendance. And it is important to note that the inventors propose the air which passes through the tea in the last stage to be, although perfectly dry, much cooler than is ordinarily used. This, however, need not be done, as the temperature can be regulated, but will be at the discretion of the tea-maker. The machine is now on its way out and will be erected by Mr. Dalgarno of Messrs. Marshall and sons, and as this gentleman is an experienced tea planter and engineer, we may be sure that it will lose nothing at his hands. It will be thoroughly tried this season, and its trials will be awaited with much interest. If successful, which it cannot fail to be, I think, it will be by far the best tea-drier in the market.

We have now fully considered tea drying machinery, and I can only say in conclusion that the very great advantages of drying by some apparatus which will economize space and thus save the cost of large buildings, must be at once apparent. Not long since I made the plans of a tea-house to make annually 12,000 to 15,000 maunds of tea. Twelve Excelsior Rolling Machines were to be used and no less than thirty-six Siroccos. The reader can picture to himself what an immense drying house would be required if the tea from the twelve rolling machines, like the Excelsior, had to be dried over the old-fashioned *choolas*.

THE BARRY AND GIBB TEA DRIER is thus noticed in a series of articles in the *Indigo and Tea Planters' Gazette* :—

We will now proceed to consider a drying machine which turns out a large quantity of *pucca* tea, and is also continuous in its feeding and discharging. The drying portion of the Barry and Gibb machine consists of a long cylinder placed at a slope. By means of machinery it is made to revolve. The leaf is fed in through a hopper at the higher end of the revolving cylinder. As the cylinder revolves, the leaf is constantly turned over and naturally tends to approach the lower end of the cylinder, but is prevented from doing so too rapidly by projecting metal webs or cells in the interior. It gradually travels down the cylinder, becoming drier in its progress through the action of a current of hot air (coke or charcoal gases may be used) which meets it, being forced by a fan into the lower end of the revolving cylinder. It is discharged as *pucca* tea at the lower end of the cylinder. This machine turns out a lot of tea and is a good deal used. Some people object to it, however, on the grounds that it is impossible to observe the condition of the tea in it, and thus to regulate the quantity supplied or the speed at which the machine should be driven, and that thus the tea sometimes comes out not perfectly dry, and at other times is longer in the cylinder than necessary. It seems, however, to fulfil many of the essentials of a good drying apparatus, and there are many testimonials of tea-makers in its favour.

TEA MACHINERY—SIFTING MACHINERY, &c.

(From the *Indigo and Tea Planters' Gazette.*)

The leaves selected by the pickers when plucking the tea bushes are the youngest and tenderest on the bush, including the young unopened leaf forming the extremity of the shoot and known as the tip. The leaves plucked are not of equal size and fineness, and form coarser and finer teas, the young fresh tip forming the finest tea of all. Tea users drink different qualities of tea as their tastes or their means incline them, and it therefore becomes necessary to separate the finer from the coarser teas to meet the market demands. It is difficult and very expensive to do this with the newly-plucked leaf, so the sifting or separating process is usually left till after the tea has been dried; although there are many who partially sift out their finer leaf whilst the tea is being rolled. This they do by giving the leaf a partial roll, say, for about two-thirds the usual time, then taking it out and putting it into a large revolving cylinder of bamboo net work. A good deal, but not nearly all, of the tip and finer leaf is sifted out here. The rest of the leaf is returned to the machine and rolled up, whilst the tip and finer leaf is rolled by hand; or, if a bag machine is used, it is put into a separate bag. Now I am a great advocate for this separation of the finer leaf before the drying process for two good and substantial reasons, one well-known and the other scarcely known at all, generally. The first and well-known reason is that by carefully rolling the tip and finer leaf separately and afterwards drying them separately they are not nearly so liable to be broken small. The second and not well-known reason is, that I firmly believe in *rolling the great bulk of the tea to a much greater extent than is usually done.* If this were done with the tip in the tea the tip would be discoloured and the appearance of the tea destroyed, whereas by separating it beforehand, fermenting and drying it separately its appearance is retained, and it can be returned to the tea afterwards. The reason for rolling tea to the extent I advocate is that the leaf-cells are more thoroughly broken and the sap consequently better exposed to the air. The readers may recollect that in the chapter on rolling I spoke of certain teas being rolled to such an extent that they seemed to be completely spoiled. Now the very teas to which I alluded have fetched the *highest average prices* in the London market for the past two seasons. They are not sold in India, but sent direct home. In manufacturing them the tip is not sifted out when the tea is half rolled, and consequently is blackened and its *appearance* destroyed, but it is there all the same with its flavour and strength.

The usefulness of the "cutcha" sifting machine above alluded to has been imperfectly recognized, or efforts would have been made to improve it. The process of sifting, however, is usually effected after the tea has been dried. This was formerly entirely, and is still to a certain extent, effected by hand. Scarcity of labour, the curse of the tea districts, is gradually forcing the tea-planter to adopt machinery for this process. A good

deal has been said in favour of hand-sifting as against sifting by machinery. but I am of opinion that tea is just as well sifted by a well-constructed machine as by hand, and the saving in time and labour is immense. By the careful selection of the sieves as to the size of their meshes much will be gained in the proportions of finer to coarser teas. A good sifting machine should sift quickly out the finer qualitier of teas, not allowing them to pass over with the coarser sorts, and yet at the same time it should do this with as little motion as possible so as not to take the fine black bloom off the tea and render it grey, which would bring down its price at once.

The Jacksons were amongst the first to enter the field with a tea-sifting machine. It was usually made double. A strong cast-iron framing bolted to a substantial foundation (and note that no tea machine needs a strong foundation more than a sifting machine) sustained a strong wrought iron shaft driven by a belt running on pulleys in the usual manner, and carrying on each end a disc having a crank pin. A connecting rod from each crank pin communicates a reciprocating motion to two horizontal frames of wrought iron, which rest on iron legs, so arranged as to rock when the frame is moved backwards and forwards. Each frame is divided into six compartments by cross pieces, and these compartments have a wooden bottom with a hole in it and a tin shoot to convey away the sifted tea. In each of these compartments is placed a sieve which, as soon as the machine is set in motion, bumps violently against the cross pieces and thus shakes the tea through. There was a modified form of this machine which had a regular crank instead of discs, and a long wooden connecting rod which drove both the trames. It was cheaper than the other, and notwithstanding this, was in my opinion better. I certainly used to prefer it.

The objections to this form of sifter were that the tea had to be lifted into the various sieves again after each operation, that for the power expended it did very little work, and last but not least, that it kicked up such a horrible noise in the tea-house with twelve sieves bumping back and forward ninety times a minute that speech anywhere in its vicinity was out of the question. It necessarily required a lot of attendance to change the teas from sieve to sieve. A much simpler and more effective machine was introduced by Mr. Dalgarno, now of Marshall and Sons, which is to be seen at work still in several of the Darjeeling gardens. It consisted of a long double sieve, about eleven feet long by two feet broad, and driven in the same way as Jackson's, by cranks or discs. The sieves were placed slightly on an inclined plane so that the tea worked gradually down from the higher end to the lower, the finer tea falling through the meshes on to the lower sieve, and the coarser being discharged at the bottom end, sufficient space was left between the two trays to allow the hand and arm of the attendant to pass in, to break the tea through if necessary. Another pair of sieves was sometimes placed alongside of this pair and sometimes in a line with it tandem fashion. This machine did its work well, with little noise, and only two women to attend it. The only objection to it is the lifting the tea into the second frame to go over the finer sieves. It does not rock on legs like Jackson's machine, but is suspended by wooden springs, flat pieces of thin sâl or other elastic wood. I highly approve of this machine. It is cheap, as all the wood-work and the sieves can be made on the factory. All one requires to purchase is the crank shaft with its necessary driving pulleys.

SIFTING MACHINERY.

Mr. Charles Ausell of Kurseong has invented a larger and more powerful machine which obtained, and deservedly, the gold medal at the late Calcutta Exhibition. In it all the sifting is done in one operation, there being no less than five sieves in the machine. This consists of a large substantial wooden frame-work strongly fastened together. In it are suspended five trays or sieves about eleven feet long by twenty-two inches in breadth, fastened together by strong flat iron bars. These trays are suspended to the top of the machine by iron springs. They are placed slightly inclined, and the inclination of each tray is in the opposite direction to the next one, so that the tea travels backward and forward in its progress through the machine. One of the sifting trays is connected to a crank which gives it the necessary shaking motion, and as all the sieves are connected, they shake together. A fan at one end sends a current of air against the tea when falling from the first sieve to the second and blows the dust out of it. The current of air from this fan can be regulated by means of cone pulleys on which the driving belt of the fan travels. The tea is fed on to the top sieve from a hopper which shakes with the machine, and thus gives a regular and constant supply. The sieves of the machine can be changed quickly and easily. It delivers five kinds of tea, namely, broken pekoe, pekoe, pekoe souchong, souchong and congou. The quantity it turns out is very large, and it is admirably suited for a large factory. Great care should be taken with the foundation of this machine. Holding down bolts are supplied with it, and these should be put through two heavy timber sleepers sunk to a sufficient depth in the ground to allow the bottom of the machine to be about two inches above the level of the tea-house floor, so that the floor may be gradually sloped away on all sides from the machine. This is a great help in sweeping up and keeping clean round the machine, and I put down *all* tea machinery like this. The inside of the lower part of framing should be filled up level with the top of the lower beam with rubble and cement. This saves all difficulty in sweeping away the tea from below the last sieve. Indeed, in the last few Ausell's and other sifters which I have put down I have sunk the bottom part of the framing into the concrete which forms the tea-house floor, just keeping the top of the beam forming the lower framing two inches above the surrounding ground level and sloping away the cement floor to the surrounding level by a gradual slope of three to four feet all round the machine ; filling up of course the inside with concrete. This is an excellent, firm and cleanly way of putting down this machine.

An excellent machine was shown at the late Calcutta Exhibition by the Jacksons on Messrs. Marshall & Sons' stand, and which is styled by them the Eureka Sifter. This consists of three sifting trays placed one above the other and parallel to each other. They are fastened securely at each end to brackets and suspended by steel springs which stand upright in pairs at each end of the machine on a pair of longitudinal sleeper which form the foundation. The motion is given by the usual crank and connecting rod, the latter being longer than usual and attached to the machine below the centre of the bottom tray. By means of this crank and connecting rod, the latter being longer than usual and attached to the machine below the centre of the bottom tray. By means of this crank and connecting rod the whole machine is set in rapid motion, swinging back and forward on the four springs which act like legs to it. The tea which falls through the meshes of the top sieve (No. 6) is, by a peculiar apparatus, caused to travel backward to the head of the machine again, where it falls on a No. 8 sieve. Whatever falls through the No. 8 is in like manner caused to travel up the machine again, and at the head of it to fall on a No. 6. These sieves can of course be altered to other numbers if desired. The method by which the tea is made to travel backwards and uphill is very ingenious. The tea falls upon a sheet of galvanized iron which is corrugated, the corrugations having a peculiar section. Each corrugation is rectilinear, and consists of a long sloping side and a short perpendicular one, the long sloping side forming the hypothenuse of a right-angled triangle, and the short side the perpendicular. The sloping side is presented to the ascending tea which, by the motion of the machine, is made to easily slide up it over the corrugation, but is prevented from returning by the perpendicular side. The tea is thus made to travel from the lower end of the machine to the upper or feeding end, where it drops upon the next lower sieve. The sieves are of the very convenient size of eleven feet by two, and the whole machine is remarkably strong and compact. I have never seen it work, as it is quite a new thing, but I fancy it will be a great success. The inventors advertize it as capable of turning out 1,600 to 2,000 pounds of tea per day with two attendants.

BREAKING AND EQUALIZING TEA MACHINERY.

The Messrs. Jackson have invented an equalizing machine which is a good deal used. It consists of two cylinders of sieve wire, one fixed in a strong cast-iron frame and the other revolving within it, being driven either by hand or by a belt and pulley. The bearings on which the shaft which carries the revolving wire cylinder are hung are made adjustable, so that the pressure on the tea may be regulated as required. The tea is fed into the machine through a hopper on the top, and passes rapidly through the cylinders. It turns out a large quantity of work, and is very efficient in equalizing the coarse teas. It is said, however, by some persons to take the bloom off the tea, so the inventors have also put into the market another machine for the same purpose, which is considered by many to be preferable to the former. In a strong iron frame-work there are mounted two cast-iron rollers which are grooved or indented on their surfaces. The space between them can be increased or diminished as required, and in passing through this machine the tea is *cut*, not rubbed small. The cutting process is preferable in any equalizing machine than rubbing the tea through the sieves, as it is almost self-evident that rubbing or crumbling the tea must make a lot of dust and rub the black colour off the outside of the tea known in the trade as the *bloom*. The tea becomes *grey* and loses in appearance and price. This is very important, and much attention is paid by a careful manager to this point; agents also insist very strongly on the proportions of coarse teas and dust being kept down as low as possible.

Mr. Ansell, of Kuresong, whom I mentioned before as the inventor of a very excellent sifting machine, has invented a very good breaker, very simple in construction and easily driven. It has the drawback however of making dust according to some of its users. It is somewhat difficult to describe without a sketch, but if the reader can imagine a large wooden gridiron moving backwards and forwards on the top of a table, the tea being fed into it through the wooden bars of the gridiron and broken by being rubbed by them on the table, an idea of the machine may be formed. Some of the very best tea-makers I know are very much in favour of this machine. Some again complain that it makes dust. I am of opinion that a good deal would depend on the shape given to the edges of the wooden bars. One thing I know from personal observation is, that it puts through a very large quantity of tea.

An excellent tea-breaking machine is much used in Assam for which Messrs. Begg, Dunlop & Co. are agents, namely, Mr. George Reid's invention. The principle of working in it is cutting the leaf between toothed rollers. There is a sieve however to prevent any coarse leaf from escaping uncut from the machine. It is spoken very highly of by some of the most prominent managers in Assam, and does its work excellently. I think the great secret of the successful working of Mr. Reid's machine is in the great speed at which it is driven, namely, 250 to 300 revolutions per minute. The tea has no time to be rubbed at this very high speed, but is broken and sent through the machine at once. The machine is very strongly made and compact, and the price is very moderate.

In many tea-houses there is to be found a circular saw useful for cutting planks for tea-boxes, firewood billets, &c. The Messrs. Marshall make these in three sizes, of which I think the one best adapted to the tea planter's use is the No. 2 size. A slack pulley and lever to stop the saw should invariably be ordered. There is also a diagonal motion attached to the parallel fence for feather edge cutting, and as some tea-boxes are now made with leather edged pieces of wood at their corners, this also would be found useful to them.

The following letter on repacking Indian teas in London appears in the *Home and Colonial Mail*:—

Sir,—As a tea planter, permit me to give vent to a few remarks on the existing system of selling teas on the London market.

To a planter an insight into the existing conditions is nothing less than exasperating. This statement may appear uncalled-for to those who have never seen the care bestowed upon the packing of tea on the tea plantations. Let me explain the position: On visiting the warehouses in which our teas are bulked in London, previous to sale, I found heaps of tea lying about, covered with a thick brown layer of tea-dust, and exposed to the damp draught of opened windows through which the London fog had free right of entry. In one warehouse only I found any mechanical appliance for rapid bulking under favourable conditions as to protection from damp. In that warehouse there was only one such appliance, and this did not nearly meet the requirements; consequently, in many rooms, tea was also being bulked on the floors under the old exposed conditions. A second bulking machine, it is true, was in process of erection, but I question if, even with that assistance, the whole of the bulking in that warehouse will be provided for. Granted for the sake of argument, that out of the numerous warehouses one does bulk the teas with the least possible exposure, this is but one step in the right direction. A vast amount of tea must be deteriorated pennies per lb. at the other warehouses, by the old-fashioned heap-system of bulking. Let what may be said to the contrary, I have good authority for saying that the heaps of tea frequently lie exposed for days before being repacked, viz., until it suits the convenience of some official to be present at the weighing. This may not appear to people on this side such an outrage on quality as it does to a tea planter. To the latter it is no less irritating than to a connoisseur would be the leaving champagne uncorked for a week when bottling it.

Let me explain that to pack his teas super-heated, and so hot that his hand cannot comfortably remain inserted in tea, then to see it leaded and soldered down whilst *hot*, is esteemed a duty of the highest importance by every Indian tea-maker. The greatest care is taken to super-heat the tea before packing to ensure the absence of damp. This very super-heating renders the tea so treated all the more absorptive on exposure. The planter knows this, and as he knows also, that most of his aroma and "nose," as it is called, depends upon the conveyance of his teas in their super-dried condition, he pays particular attention to the soldering and fastening down of the chests. To such an extreme of caution is this carried that a carpenter, against whom it could be proved that he had driven a nail through the lead whilst nailing down the lid, would be fined on many plantations. Now sir, after having for years devoted much care and labour to thus shipping his teas at perfection point, what must be a planter's feelings on seeing his labour wasted through carelessness on this side, a carelessness so efficient—permit the expression—that his teas are placed on the market in the very worst possible condition, not to be actually unsound? Teas cannot be turned out of a chest and left exposed for half-an-hour to London fog, without being damaged, if they are repacked *cold*. Teas left exposed on a floor all all night, will travel all the way between the super-dry state and the state of the surrounding atmosphere, sometimes damp enough in London. Once this absorption has taken place, the damage to aroma and "nose" has been done, and pennies per lb. have been taken off the value. When it is remembered that these teas could have much of their aroma and "nose" returned to them by being super-heated again, after bulking, immediately before repacking, why is this not done? It would pay handsomely, provided the teas were repacked in properly soldered down chests, instead of as at present in part paper part lead, unsoldered, and wholly exposed.

This latter is another of the existing evils, and deserves to be noted, though remedying it would only be a comparative success, unless the more heinous crime of repacking the teas *cold* had been removed. As this question refers to thousand of pounds lost annually in the way indicated, perhaps you will pardon this lengthy epistle from AN OLD PLANTER.

P.S.—One word as to the state in which the chests are too often offered to the buyers here. The chests after the process of bulking and repacking—save the mark—as permitted at present, are barely recognizable as the same packages despatched, so neatly and trimly finished off from the gardens. Broken, bulging and patched with paper lining to replace the damaged lead, and no attempt at rendering the contents atmosphere, or even weather, proof; such is the end of all the planter's efforts and the state in which his teas reach the buyers in far too many instances.—A. O. P.

Our Jorhat correspondent writes:—Your excellent leader anent grogshops in the tea districts is very much

to the point. Planters would be only too glad if Government would direct a little of that paternal attention now given to the compiling of countless forms and restrictions *ad nauseam* to this real grievance. One that de, roands redress, if not for the sake of the planter for the sake of the unfortunate coolie whose welfare Government assures us it has at heart. Most of the rows and disputes that occur on a tea garden may be put down to the presence of those nefarious grogshops. Many a case of assault, arising from drink, is settled by the planter himself, (not without bother,) to save the trouble and expense of going into court, but more serious cases where lethal weapons are used, have to be tried before the Magistrate, and entail the loss to the estate of perhaps several coolies' labour for some days, if the court is situated any distance. It seems strange that a Government professing such a paternal regard for our coolies' welfare and hedging them t round with every *minutiæ* of red tapeism, should at the same time place at their doorsteps shops, where poison adulterated with water can be had for a mere song.

We aro having rain here pretty well every day. Leaf is coming out at last, though not so fast as to keep pace with our wishes. Most concerns are now behind and falling behind last season. The tea made this May will be little if any more than was made in April. Blister blight, red spider and caterpillars have been having more than a day of it. How many blights besides Government has tea to contend against.

LEAF-DISEASE AND ITS EFFECTS IN JAVA.

Naturally enough, our neighbours in the "Netherlands India" colony were very unwilling to admit that the coffee fungus threatened to become as serious an evil in their land of rich lava soil surrounded by an atmosphere of volcanic gases, as it has proved to be in Ceylon and British India. But the fatal truth cannot any longer be blinked. We recently copied an alarming paragraph from a Java paper, and this mail brings statements of reductions in estimates of crops, owing to the ravages of the fungus, in the east as well as the west of the colony, such reductions being regarded as merely preliminary. From the moment we saw the fearful condition of the Liberian coffee nurseries at Buitenzorg, added to fatal spots on leaves of *Coffea Arabica*, we never doubted what the end would be, and we suspect that for the present at least and until the evil disappears or is modified, Java has seen the culmination of her coffee crops, and will follow Ceylon in the process of decadence. The game would, therefore, seem to be in the hand of Brazil, but although the South American Empire is, *as yet*, free from *Hemileia vastatrix*, she has an equivalent in the commencement of the slavery crisis. Nor is the coffee free from serious disease, on roots and leaves. The most recent development has been the scale insect, our "black bug," from which serious mischief was anticipated It would ill-become us to rejoice in the misfortunes of our neighbours, but it is right, we should appreciate facts and their importance. We can not forget that Brazil has swamped competitiors by means of a wicked and unfair system of compulsory labour and part of the inevitable retribution is that Brazil has largely swamped herself in the process of ruining others.

KEW GARDENS TO COLONIAL OFFICE ON TIMBER FOR TEA BOXES IN CHINA.

Royal Gardens, Kew, 30th April, 1884.

SIR,—With reference to my letters of March 29th and April 14th, on the subject of the wood used in China for tea chests, I am desired by Sir Joseph Hooker to inform you that he has received from the Foreign Office further reports furnished by Her Majesty's Consular Officers in China upon this subject.

Without further troubling you with copies of these documents in detail, I may now sum up the conclusions which have been arrived at from their study in this establishment.

The wood most esteemed for the purpose is evidently that of one or more species of *Liquidambar*. Probably that most used is the wood of *L. formosana*, (Hance), a species apparently common in South China. The inquiry has however disclosed the existence of two other species in China, and of one of these—*L. acerifolia*, Maxim—the wood is used for tea chests in China.

With regard to the information contained in Mr. Currie's letter of March 28th, of which a copy was communicated to you on March 29th, I am to say that the specimen sent by Mr. Sinclair as an example of the wood used for tea chests at Foo-chow-foo is almost certainly the wood of a *Liquidambar*, and not, as stated by him, of *Pinus sinensis*. The wood referred to by Mr. Consul Oxenham as used at Chinkiang under the name of chestnut is probably also *Liquidambar*, as the Chinese, owing to the resemblance of the fruit, seem to regard them as related. The wood of *Liquidambar* is undoubtedly used for the purpose at Kuikiang and Shanghai, while at Hankow the wood of the species, which has been identified as *Liquidambar acerifolia* (Maxim), is largely employed. At the latter place deal (probably the wood of *Pinus sinensis*) is used, and also at Tamsuy. At Swatow and Ningpo boxes are made from the wood of species of *Cunninghamia*. Elsewhere, the woods of willow and of *Sophora japonica* are employed.—I am, &c.,

W. T. THISELTON DYER.

The Hon. R. H. Meade, Colonial Office.

AVERAGE PRICES OF TEA AND LOCAL SALES.

There is all the difference in the world between fine plucking and coarse, just the difference between quality and quantity. The low prices realized by an invoice of tea prepared by a Ceylon tea-maker of no mean reputation having attracted attention and discussion, we were assured that the result was entirely due to the determination of the gentleman in question, from which no remonstrances could move him, to pluck copiously or, as his critics insisted, coarsely. In contrast to this case we have heard of two young estates which are plucked so finely that the averages opposite those estates in the London market are fully twice and more the price realized by the teas of the free plucker. It is quite possible, however,—very probable indeed—that the money results are in favour of the latter. But his competitors may be willing to sacrifice present profit in order to "gain a good name for their estates." Such name may possibly help to sell the estates if sale is desired, but the estimate of the London brokers will certainly be formed on all-round breaks of teas. Some make a large proportion of pekoe and a small quantity of pekoe souchong, but it is curious to notice how matters are equalized by the lower prices given for what is called pekoe. The averages given by Messrs. Thompson and others will only be accurate when all estates forward the whole of their teas and of all qualities from picked orange pekoe to broken tea and dust for sale. That tea can be made without dust resulting has been asserted, but we do not believe the assertion. While some send all their teas from finest pekoe to dust to market and others withhold broken tea and dust, we submit that averages should be calculated on pekoe, broken pekoe and pekoe souchong, to the exclusion of fancy pekoes at the one end and dust at the other. What is done with the inferior leaf and dust on some estates is shown by the entry in last reported sales: "Ceylon tea, which realized only an average of 4¼d." Whether

the owner shipped this stuff himself or, as is more likely, sold it to some dealer who has tried his chances in the London market, the price realized certainly could not pay the exporter, even if he only paid 2d per lb. Like a great deal of the twig cinchona bark exported of late years, it would have been more profitable to have buried or burnt the stuff called "Ceylon Tea." Every person interested in the reputation of Ceylon tea is bound to do his best to prevent this sort of thing from being repeated. The exclusion of all inferior tea from an invoice gives the owner of that invoice an unfair advantage over competitors, while ALL Ceylon tea is damaged in reputation by the low figure against rejected stuff which is called "Ceylon Tea." What is wanted here as well as in India is a local market amongst the natives for teas, which, although classed comparatively as inferior, are good and wholesome. Indeed there are many European tea-drinkers who give a decided preference to dust. The difficulty would be that persons purchasing professedly for local retail sales might follow the example already set and try the English market. The miserable price realized, however, ought to prevent this. Some day the Sinhalese and Tamils of Ceylon, as well as the Hindus and Muhammadans of India, will be a tea-drinking people and consume the so-called inferior teas, and meantime a writer in the *Indigo and Tea Planters' Gazette* indicates that it would pay the tea planters to unite and agree to sell their inferior teas at a loss locally rather than load the London market with them. The arguments used are as follows :—

Our correspondent T. considers that little or no help can be gained from selling teas in the local Indian bazaar at four annas. We beg to differ from him, and we feel assured that if Indian tea is to pay at all in the future, of which we have no doubt, a considerable proportion must pass the hammer at four annas. The planter, the agent, and every one connected with tea must make it their aim and object to be able to lay teas in Calcutta at an average of six annas [say 36 cents.—ED. C. O.] per lb. In order to effect this and to thoroughly discuss the matter, it will perhaps be best to divide the expenditure into local and Calcutta charges. To enable the planter, therefore, to lay the teas down in Calcutta at six annas per lb., the local expenditure should not exceed 4 annas (say 24 cents) per lb., and this leaves 2 annas (6 cents) for Calcutta charges which we mean to include all agency charges, brokerage, and in fact everything that is necessary to be done in connection with the article in Calcutta. In order to effect this end the planter will have to give a very large outturn per acre. Assuming that it takes from 80 to 100 rupees per acre to cover local expenditure, and another 25 per cent. for Calcutta expenditure, taking the former calculation of R80 per acre for local and 25 per cent. for Calcutta expenditure, the total expenditure would run to say R100 per acre, and with tea at six annas per lb. would necessitate a crop of very nearly four maunds per acre to cover expenses and to give a profit at least 5 maunds per acre. This outturn is we believe considerably over the average supposed yield of existing tea gardens, although many individual gardens give considerably more. In order to give such a large yield naturally the plucking cannot be very fine, and there must be a considerable quantity of tea sold out of such a crop at 4 to 5 annas per lb., and we ask our readers if we are to go on this basis whether a considerable relief would not be felt, were, say, 10 million pounds of these lower grades passed off in Indian bazaars? It must not be left out of consideration that all brokers have invariably given it as their opinion that the *lower grades* of Indian teas are always held down to a certain level in price by the grocer, dealer or middleman, always being able to supply himself with equally good values in China lines. It is to the higher grades of Indian tea *which are unobtainable* in China teas that we must look to run up our averages; so that to get rid of our lower class teas, which come into more immediate contact with China, must be our chief aim and object. We think that there is little doubt but that for the finer lines of Indian teas a better market will always be obtainable in London than any other market. Our correspondent T. considers that four annas would not pay for our low class but "*sound*" teas. We do not contend that it "will pay," but we think it might be made to cover expenses. However, we doubt if it would ever be sold at anything like that amount. We ourselves have bought China tea in one of the up-country bazaars done up in a neat little box, with Chinese characters, but for two ounces we had to pay 3 as., allowing for the usual commission, which all servants will take, we imagine the cost would be at least 2½ as., and this for two ounces, or at the rate of one rupee four annas per lb. For another kind a lower class much resembling snuff 6 pice, from all that we could learn, was the bazaar rate, so that even taking that, it gives a return of 10 as., per lb. No doubt the native Mahajan expects a very large profit, but if even 6 as., per lb. could be got for say 10 per cent of our Indian crop, what would the effect be upon the London Market? At present stocks are something like 29 millions, and if ten per cent of the Indian tea crop were deducted from that, it would reduce these to something like 23 millions or a little over 4 months' supplies, which would leave a comparatively small quantity. It may appear to some of our readers that we are taking a peculiar view of matters, but we would beg to refer them to our contemporary, the *Home and Colonial Mail* of the the 25th April, where they will see that in an invoice of the Assam Company "Our Commissioner in the Lane" reported 2,300 chests Assam Company sold from 6½d to 1s 5d 50 per cent being broken tea. If it pay the Assam Company to ship and sell teas at 6½d per lb., putting freight, boxes and other charges against the extra trouble of setting it up in four ounces packets to be sold in our local bazaars, it would have paid, we contend, better to have sold it here on the spot rather than ship it to London, because it would have saved the London Market, and we think that probably a little better values would have been obtainable for the finer lines. We are as anxious as any of our readers to see full and good values for Indian teas, but we are convinced that better values are only to be obtained by opening up markets for our lower grade teas. China and India are now running a race, and if China teas can be sold in London at 4d per lb., we see no reason why Indian with superior appliances for turning out the article in the way of machinery, should not be able to run in the race and win. It seems rather absurd for China to send an ounce of tea to India, still it does it, and if natives take to China tea, why should they not take to Indian tea? We feel convinced that it has only to be pushed to become a success. Were the India Tea Syndicate to ask the agents of tea concerns in Calcutta, we feel sure that they would contribute in as liberal a manner as they did to the Australian venture. There can be little doubt that the amount of tea sent to Australia had an excellent effect on the London Market, and although at the time it seemed in a manner to be sacrificed, good fruit was borne from it, yet we did not send our best lines to Australia. We believe that with a little fostering care a larger amount could be moved off in the Indian bazaars, not to speak of the Commissariat, in one season than Australia will take in two, and we feel that anything we can write on the subject cannot be too strong if it tends in the smallest degree to hasten the much wished for result.

We commend the statements above made to the attention of tea planters in Ceylon. When we mentioned average yields of 700, 600, and 500 lb. per acre the other day for estates in Ceylon at various altitudes, we of course referred to flush-picking on the ordinary principle of the bud, the two leaves next below it and half the leaf below those two. Anything less than this must be regarded as fancy picking; anything more as coarse. Of course, there are occasions, such as a plucking before pruning, where a more severe process than ordinary is likely to be indulged in—a "stripping" process That we know was the case as regards a large invoice for which prices at a recent sale varied from 2s 6d for fine pekoe to 7½d for dust. The average of 1s 1d in that case

was all that was anticipated and will pay well; but it is clear that if the 7½d tea could have been sold locally for 6d, it would have paid better and the London average for the estate would have been higher. We might urge an association of tea planters, pledged to sell all their inferior teas at low prices for local consumption, but we have the example of the cinnamon chips case before us, and then if all agreed, how could a purchaser be prevented from exporting instead of retailing locally?

CULTURE BY IRRIGATION AND OTHERWISE IN CEYLON.

Sir John Coode, in connection with this subject (p. 33), showed that Ceylon was liable to floods as well as deficiencies of water, but his reference to the number of houses destroyed requires much the same sort of correction which Mr. John Ferguson supplied in regard to the popular impression of native laziness because agriculturists, who may have spent a night in work on their fields, are seen resting or sleeping in the daytime. The "houses" destroyed by floods are mainly wattle and daub huts, the earth of which melts away as the water saturates it. Such huts are rapidly, and at a small expenditure of labour, restored. Sir John Douglas's characteristic story of his being reduced to the painful necessity of performing his ablutions in soda water, is calculated to remind one of the Princess who, when she heard her father's subjects were dying for want of bread, asked why they did not eat pie-crust. It is of importance to remember however, that, in conducting the pure water of the Matale mountain ranges to such a place as Anuradhapura, we are supplying, not only means of irrigating corn-land but pure drinking fluid on which health and life so much depend. It is new to us that any of our engineers erred in the direction of attempting to make water run uphill, but we knew of such large works as Kantalay tank at Trincomalee and the Tissamaharama near Hambantota being restored on the most correct principles of hydraulic engineering and yet unsuccessful, because they failed in attracting population as was expected. It is highly scientific hydraulic engineers like Mr. Henry Parker, too, who have vindicated the wonderful skill of the Sinhalese engineers against the impeachment recorded by Tennent. Mr. Parker and others like him, who are doing good work "far in the wilds, unknown to public fame," will appreciate the cordial testimony to their merits and usefulness borne by Mr. Bruce. Mr. John Ferguson's very able summing-up of the whole question of the varied agriculture of Ceylon, we leave to speak for itself. We would only repeat what we previously remarked—that, even if we must continue (as we believe we must) to depend on continental India for a large portion of our grain-supply, the duty is none the less urgent of enabling a place remote from the seaborde like the North-Central Province to grow supplies of food for the consumption of the inhabitants. No imported paddy could be sold at 50 cents or three times that price per bushel, and it certainly looks as if the North-Central Province were destined to become an exporter of rice to a considerable extent. We consider it the duty of Government to give all legitimate encouragement to rice-growing, and we did not complain when Sir William Gregory, to save the parangi-smitten people of the North-Central Province, gave them great irrigation works out of revenue avowedly derived from European planters. But we cannot possibly agree with the angry philanthropist of the local "Times" who wouldgive grain-growers land for nothing and supply them with irrigation water at the expense of others. Whether in money where money is available, or labour where money is scarce, those who profit by rice culture should pay a fair price for land and also for water which Government provides, giving them sluices and engineering skill gratis. The taxes on grain and salt are about the only taxes which a large proportion of the natives pay, and Government is savagely denounced for not giving up revenue which can be used for the general good but which could not possibly be replaced. We consider the Government policy towards the grain-growers of Ceylon as erring rather in liberality than the reverse.

IRON AND STEEL RAILS.—The almost complete extinction of the iron rail trade is shown by the enormous fall in the exports of that class of rails. A few years ago the bulk of rail exports were declared as iron rails, but the special return issued by the Board of Trade shows that they now form a very small percentage of the total. In 1876, the iron rails exceeded in quantity the steel rails, but since that time the proportion of the latter has been rapidly increasing; and by the official return to which reference has been made, it is shown that while in the first four months of last year the quantity of iron rails exported was 11,087 tons, for the same period of the present year the exports amounted to only 4,149 tons—a small part only of the total of rails. The steel rail trade has in the same period showed a falling-off, but in the four months of the present year as much as 171,355 tons of steel rails were exported. During the same period of last year the exports were 246,536 tons. The chief falling-off this year is in the exports to Italy, Mexico, the United States, the Argentine Republic, and the East Indies. It is also noticeable that Russia, Germany, and Holland have for the present almost ceased to buy rails of either kind from us, if the experience of the first four months of the year is a test.—London *Times*.

MONKEYS TRAINED TO PLUCK RIPE COCONUTS.—Inquiry was made through your columns, some time back, about the truth of the piece of information from the Straits respecting the services of trained monkeys employed in plucking ripe coconuts. The following extract from Carl Bock's "Head Hunters of Borneo," confirms the truth of the story:—"On my inquiry whether the monkey was trained to 'perform,' and promising a few cents for the entertainment, the man spoke a few words in Malay to the animal, which immediately began to climb a tall coconut palm close by, which I roughly estimated to be from forty to fifty feet high. When about one-third the distance up the tree, he stopped and looked down at his master, who as a signal pulled the rope, when again master Jackie nimbly climbed a few feet higher, again stopping to rest and indulge in playful tricks. At last he reached the crown of the tree, felt at several nuts one after the other till he came to a ripe one, which he pulled off and threw down to the ground. Still carefully testing the fruit, he pulled several ripe ones tossing them down in a quiet business-like manner till a nod from his master told him he had enough, when he quietly came down. I was told the Malay went from village to village, and made his living by employing the monkey's cleverness to collect the cocoanuts in the plantations as a regular business. He wanted twelve florins for his pet, a low price for so clever an animal. I afterwards found that monkeys so trained were not at all uncommon." See pp. 266-67.—*Cor.*

MY FLOWER GARDEN IN THE DECCAN.

During the whole of my life I have been an amateur floriculturist, and in whatever tropical climate my lines have been cast there I have managed, under more or less disadvantages, to raise a few flowers, differing from or superior to those growing around. But, strange as it may appear, the place where I obtained the greatest success and had the most charming and perfect varieties of blooms was at Secunderabad, in the Nizam's territory in the Deccan of India, and where I had to contend against difficulties unknown before. True that for four months of the year the temperature of the station was cool and moist, but for the remaining eight either the periodical rains swamped, or the scorching hot winds and sun dried up every atom of delicate vegetation. Then again the soil was the poorest of the poor—sand, or rather pulverised granitic rock, being its chief component, and the labour available was the least expert I had hitherto had the misfortune to deal with. Your Indian *mahlee*—such being the name of the native gardener—is, as a rule, an ignorant coolie, knowing little of the practice and less of the principles of his occupation, which he only follows, as it is his caste—easte, the bogie despot of the East. Moreover, he is a gentleman who scorns to be taught, strive you ever so much to teach him.

But before I enter into any details as to how—drawbacks notwithstanding—I produced flowers which would have held their own with those of many a European grower, let me give the reader an idea of the spot where this cultivation was carried on—my house and grounds to wit. Of the former I shall merely say, that it was large and substantial, and stood within an inclosure—*compound* is the generic term—of a coarse grass, indigenous to this portion of the Deccan. A thin belt of shrubs and trees skirted the frontage of the bungalow; among the former some Crotons, Hibiscuses, Mimosas, Lantanas, and Oleanders; among the latter, flowering but fruitless, Pomegranates, a wide-spreading Neem (Melia Azadirachta), a ditto Tamarind, and a Moringa pterygosperma, that tree whereof the root is the substitute for Horse Radish, the seed pods the "stick curry" of *gourmets*, and the seeds themselves the "Ben Nut," yielding the oil used in perfumery. An undergrowth of a sort of yellow flowering dwarf Leguminous plant, relieved by several bright-leaved Poinsettias and variegated Laurel, and by many a bush of the ubiquitous Marvel of Peru, or Four o'Clock Flower, and Plumbago, filled up the ground space between the trees and shrubs, which, however, could not be said to flourish well, Mother Earth being, as before mentioned, so sadly wanting in elements of nutrition.

How, then, did I manage to grow flowers sufficiently worthy in points of speciality to be chatted about in this journal? Wholly and solely by cultivating them in pots from their alpha and omega—from seeding to maturity. I shall take but one instance, and that the rare and choice Convolvuli and Ipomœas I possessed, and which, indeed, were the raree show of my garden. Sowed in pots, and fit for removal, I carried them to and arranged them around the pillars which supported the portico of the house, there to trail up a latticework of cane. Growing as they did in rich mould, their upspring was amazingly rapid even for Convolvuli in a hot climate, and presently they literally dazzled the eye with the variety, the colouring, and the numbers of their bloom, which *embarass de richesse* had indeed to be toned down with Jasmine, Honeysuckle, and a climbing Rose or two, all having been previously raised in pots and brought into their present position. So, to be poetical, I could fairly say—

> "O'er the porch the wild Rose and the Woodbine entwined,
> And the sweet-scented Jessamine waved in the wind,"

—har always that the sun's heat causes very much of the fragrance to evaporate from the oil-cells, not only of Jasmine, but from every scented flower in the East.

A gardener from temperate zones, visiting my "compound"—the word is convenient—would have been struck by the abnormal system he saw in operation; nothing bedded out, everything "bedded" in—if I may be allowed the term—either a pot, a half tub, a keg, a cartridge barrel, or receptacle capable of holding it. I and others too who gardened in the Deccan held to the wine-bibber's view—that the liquor, being good, no matter what sort of vessel held it. And this same expert would have stared a bit as well at the arrangement of the various plant receptacles aforesaid, though he must have confessed that it was pleasing and effective. I disposed the receptacles in semi-circles, where they would show to the greatest advantage, and particularly in front of the house. To each of these semicircles there was a background of tall plants—Cannas, Salvias, Poinsettias, Coleus, Tobacco—nay, even of feathery branched Asparagus. One has no idea until one tests it, what an elegant mass of light foliage the "sprays" of Asparagus make. In front of this "backing" stood a large tub painted green, or an equally large flower-pot daubed red, in which grew a Rose, or a Gardenia, or a choice Hoya, or a Stephanotis, or indeed any flowering plant that would stand out well, and not "hide its diminished head." Then around the base of the tub or pot, but at a foot or two from it, came a closely-set-together arc of small flower-pots, in each of which was either an Aster, a Balsam, a Phlox Drummondi, a double Portulaca, a dwarf Tropæolum, an Antirrhinum, a Marigold, a Verbena, a tuft of Golden Feather; and last, but not least, a Geranium or Pelargonium, care being always taken not to mix flowers higgledy-piggledy, but to keep each kind together, and to study colours and sizes somewhat. I may assure the reader there was very considerable beauty and a little realisation of the "bedding out" in this order of plants of mine.

The Roses I cultivated were many, those that did best being the old-fashioned sorts, such as Maréchal Niel, Gloire de Dijon, Géant des Batailles, Cloth of Gold, Devoniensis, Coquette des Alpes, and so on; and it was wonderful how quickly they grew, and how profusely some of them flowered. The soil I used was a haphazard rule-of-thumb mixture of leaf-mould, stable manure, alluvial gatherings from the large fresh-water tanks, red earth—its colouring principle no doubt iron, sand, and a dash of sal ammoniac, which, in infinitesimal quantity, is a grand fertiliser, but, when too liberally given, a certain atropos to a Rose bush. The trees were wintered by laying bare the roots, and depriving them of water to a great extent during the hot season, when all vegetation is at a stand-still. The *mahlee* afore told of objected greatly to this "not gib tree panee (water) to drink, dis plenty too hot sun," and was for drenching them, but I forbade his doing so under penalty of "stick."

It was striking how quickly and splendidly, yet not without trouble, Balsams grew. I had them with huge-sized flowers, of all colours and varieties, raised from seed obtained from Carter and from Sutton. I would have matched my dwarf Camelia Balsams with any, even with renowned growers of the flower in England. Portulacas did gloriously, the double ones always recalling to my mind those rosettes one sees in the buttou-holes of officers of French and other Continental orders of knighthood. Asters, too, were an especial pride of mine, and I got much *kudos* for the dwarf Pæony Perfection, the dwarf Victoria, and the dwarf Chrysauthemum kinds I raised. It was difficult to get good Verbenas, but, *per contra*, Pelargoniums, both double and single, were really first-rate. So also Phloxes, and Snapdragons, and other annuals, which at this moment have faded from my memory. But I remembeer that Sweet Peas flowered scantily and were next akin to scentless, but Tuberoses made up for that, and were almost too powerful in perfume. Dahlias and Zinnias did fairly well; Tulips would never flower with me, nor would the Gladiolus, though I have seen it thriving in the gardens of the Nizam, near the city of Hyderabad.

Three spoilators infested my garden: one was the white ant, which got into the tubs and boxes, ate the wood, and worked its way through the soil into the roots and stems of Roses and such-like; another spoilator was the bandicot or pig-rat, who revelled upon the larger seeds and the juicy parts of succulent plants; and the third and last, and worst, was my gardener, who, for the trifling consideration of a few of the Nizam's "duls" (copper coins), would cut and sell to any lady or gentleman of the station a bouquet of my choicest blooms, at the same time taking oath to me that he knew not how my "Johns of Battles" "Cockeys of Yalpes," "Glories of the Dungeon," as he miscalled my Roses, or how my "Gasters," "Ploxes," "Snapping-up-Dragons," and other flowers had been conjured from my pots into the vases of other individuals.—H. L. C.—*Gardeners' Chronicle.*

THE TEA CONTROVERSY IN MELBOURNE.

Mr. J. Moody, of Messrs. James Henty & Co., has sent us a large mass of literature connected with adulterated and unwholesome teas, which, with the aid of such able chemists as Messrs. Newbery and Dunn, he has striven with so much pains to exclude from the Australian markets. The papers sent us show the difficulties the friends of pure teas have to contend with. People have got accustomed to the cheap and nasty stuff and will have it, not because it is good, but because its apparent cost is low: the truth being that good Indian tea at 2s 6d retail is cheaper than the China stuff which the dealers can retail at 1s 3d, a profit of 50 to 100 per cent being made, even then, on the cost price. That is the secret of the tenacity with which brokers and dealers cling to China stuff, and of the abuse they pour upon Mr. Inglis and others who say a good word for Indian tea, or dare to join Mr. Moody in speaking the truth about low or "lie" China tea. Mr. Everard was allowed to have his fling against Mr. Moody and in favour of the tea that gentleman condemned recently. But this person, who so loudly complained of "abuse" of his beloved China tea, indulged in such language regarding men like Dr. Hassell that he had to be severely reprehended by the editor of the *Age*. When Mr. Everard and men of his class in Melbourne put themselves in opposition to scientists like Messrs. Moody, Newbery and Dunn and Dr. Hassell, people in Melbourne, who know the parties are—well, no: they are not surprized, but they have their own opinion as to which side the balance is likely to strike. Slowly, it may be, but surely, the Australians will learn that Indian and Ceylon teas are not only better, but cheaper than the low quality and adulterated China stuffs.

HOW "LIE TEAS" ARE MANUFACTURED.

Melbourne, 2nd June 1884.

I duly received your kind present of "Ceylon in 1883" by John Ferguson, which I have perused with interest, especially the map showing extent of tea cultivation, and marvel at its rapid spread, though the favour with which your teas have been received in Great Britain should fully account for this.

The papers forwarded and slips enclosed will show you that I am still a staunch advocate of pure teas as against the adulterated and bad stuff called congou that comes into Melbourne, and I further have shown that the methods of detection adopted by the Customs analysts of London and Melbourne have been mastered by the able Chinese manipulator.

As usual the largest buyer of this inferior stuff is Mr. Everard, the tea broker, who also attempts its defence with the same balderdash he used to talk when you were in Melbourne.

For a length of time Messrs. Newbery and Dunn and myself, have been fully convinced that the bulk of low class China rubbish shipped to this port and London consisted of re-dried or exhausted leaves made up again to pass a standard of analysis, and, in the case of what is called here "Amalfi" teas (about 3,000 packages that have lately come forward to Melbourne by ships "Amalfi," "Potosi" "Catterthun," &c.), such had gone bad or putrid before making up, and it was attempted by high firing to cover this fault. These teas are all the same class; yet strange to say the Government analyst only stopped a very small portion and passed the balance for home consumption.

After many experiments and with the scant appliances afforded by my laboratory I have succeeded in making this Malloo tea. Taking exhausted tea leaves (or tea once used), I have added to these leaves in a concentrated form four things (for obvious reasons not disclosed) and afterwards obtained in the jargon of a tea-taster, "small, even, twisted black leaf rather strong and full infusion on pekoe flavour, richly fired with deep red infusion."

Or in the language of the customs analysts of London and Melbourne: "The tea is singularly free from mineral matter, and the high precentage of extract and soluble salts forbids the idea of adulteration and indicates a first-class tea of good strength."

If I can do this, how much better can the clever Chinese manipulator make up these spent leaves which pass freely the Custom houses of London and Melbourne. You will see by the papers I am doing my best on this side to put a stop to it; but what is being done in London?

As a phase of the tea industry that may interest you, I will forward all the papers containing notices of this "Amalfi" business.

9

QUANTITIVE RESULTS OF A CAREFUL EXAMINATION OF 100 GRAINS CONGOU TEA (SO CALLED),

Sold by Auction in Melbourne on 9th Jan. 1883.

Most respectfully dedicated to my fellow-workers in the tea trade of Victoria, with the earnest hope that they will help, with their experience and knowledge, in maintaining for our business a high standard, and use their best endeavours to promote and develop public taste for the finest qualities of tea; and because the exigencies of our poorer colonists require a commoner and cheaper article, so much more should it be obligatory, in their interests, and as far as within our power, to limit and direct the demand to pure, sound and genuine, if not high class, tea.

Competion is the soul of business, but it must be honest and straightforward; and in referring to my recent action in connection with the condemnation of 4,435 packages of tea sold lately in Melbourne, on Sydney account, and forming a portion of the 10,000 packages so sold, I must remind my readers that the catalogue of these teas was accompanied by a warranty from some analytical chemist declaring "*the tea genuine and the flavour of high class.*" With the knowledge to the contrary, my action was clear, and the means taken to sell these teas under such warranty was denounced to the importer *prior* to sale.

J. O. MOODY.

Melbourne. 15th January, 1883.

Samples taken direct from the bulk, and 100 grains weighed off, giving, after thorough examination, the following result:—

Section.	grains.	
1. Unfermented, fairly-made tea, light yellowish green to dark olive green leaves (on infusion) of various sizes—in fact, all that could be detected...	1·22	
2. Good, well-fermented, black leaves, and portions of same, all over ¼ inch long... ...	1·59	
3. Fairly-fermented black leaves, and portions of same, all over ¼ inch long...	5·16	
4. Old, overfermented, and generally low-class leaves, and portions of same, but over ¼ inch long ...	10·16	
Total genuine tea		18·13
5. Small stuff, all under ¼ inch, and containing fragments of leaves of all kinds, but those coming under section 1...		29·46
6. Dry, hard stalks, ⅛ to ⅝ inch long, extracted carefully in the dry state and no more visible to the naked eye...	7·60	
7. Tea seed, shell, husk, fragments of rice, quartz, hair, and picked out in the dry state... ...	1·60	
8. Hard stalks, ⅛ to ½ inch long, obtained after boiling the sample for one hour, and found rolled up with pieces of leaf and gum redried ...	2·16	
9. Lie tea, or leaves unmistakably not tea leaves over ¼ inch long ...	·93	

10.	Decayed, charred, rotten, perished, or partly perished and diseased leaves, all sizes ...	... 10·63	
11.	Final remnant left on filtering paper containing some tea dust, but also minute particles of decayed and rotten vegetable and animal matter, may be described as sand, dirt, and filth...	... 2·02	
			24·94
			72·53
	Loss through infusion or otherwise...		27·47
			100·00

When bending over the moist leaves spread out after continuous boiling, the smell is not at all like that of good sound tea, but rather the exact counterpart of the damp earthy smell evolved from decayed vegetable matter often noticeable during autumn months.

With regard to the scented orange pekoe (so called) and condemned by me, the examination of one sample of 100 grains gave the following result :—

		grains.	
Dry hard tea stalks...	...	15·28	
Tea seeds... ...	...	2·38	
Other rubbish, consisting of gravel, shell, husks, rice, bark, &c.	...	2·52	
Nodules, the agglutinated accretions of rubbish, but containing particles of tea	...	11·64	
		31·82	in 105

grains of tea.

Further investigation was unnecessary; the nodule is a work of art, displaying to advantage the ingenuity, patience, and thrift of the Chinese manipulator.

J. O. MOODY.

DELETERIOUS TEAS.

The Customs department dealt with the balance of the challenged teas ex "Amalfi," which were stated to be impure and unfit for human consumption, on Saturday. It will be remembered that on the previous day Mr. Langridge, acting upon the expert evidence of Messrs. Johnson and Blackett, the analytical chemists, and the advice of his responsible officers, condemned 287 half-chests of the "Amalfi" tea, for which "sight entries" had been passed at the Customs by Messrs. Charles Lister & Co., merchants. A further lot of 463 half-chests, for which a "sight entry" had been passed at the Customs by Mr. A. Harvey, were at the same time detained by the senior tea inspector, who declined to pass the consignment on the ground that the tea was deprived of its proper quality and virtue by exhaustion. Samples of the tea, four in number, were, as a matter of course, at once forwarded to the Government analytical chemist, and upon the advice of Mr. Musgrove, the secretary of Customs, the Commissioner directed an independent report to be obtained from Mr. C. R. Blackett, the object being to leave no stone unturned to enable the proper quality of the import to be promptly ascertained. Of these samples, the first, which represented a line of 130 half-chests, was described by Mr. Johnson as genuine tea. The extract was given at 25 per cent, the soluble ash at 2·1, the insoluble at 3·9, and the total at 6; and to this was added the following general note :—"Soluble ash low, but probably from natural causes. Soluble extract very low, but probably from natural causes also." Damage by sea water and adulteration were not perceptible. The second sample, representing 120 half-chests, was reported to be really tea, the extract of which was given at 25, soluble ash 2·35, insoluble 3·4, total 5·75, It was also pointed out that it was a very low cheap tea, but apparently genuine. The tea had not been mixed, stained, or coloured in any way, and there were no perceptible traces of damage by sea or fresh water. The third sample, taken from a line of 122 half-chests, was reported on in almost identical terms. The tea extract was given at 32 per cent, the soluble ash 1·85, insoluble ash 3·75, and the total 5·6. Mr. Johnson was of opinion that this was a sample of apparently genuine tea, though the soluble salt was very low. The tea extract in the fourth and last sample was given at 27 per cent, whilst the soluble ash was 1·6, the insoluble 4, and the total, 5·6. To this analysis Mr. Johnson added the following note :—"Soluble salt so low as to lead to the belief that in this case somewhat of exhaustion has taken place. Soluble extract also very low." Traces of damage by sea water or adulteration were not perceptible. Similar samples were placed in the hands of Mr. Blackett, who reported as follows :—"I have analysed the four samples of tea received under seal from you yesterday. Results as follow :—

No.		Extract.	Soluble Ash.	Insoluble Residue.	Ash.
B 87	...	28·0	2·3	3·0	5·3
B 88	...	28·8	2·3	3·0	5·3
B 89	...	28·0	2·5	2·7	5·2
B 90	...	27·4	2·4	2·7	5·1

Free from sand and foreign matters; no evidence of sophistication; not exhausted; common quality."

After carefully examining into the whole matter, the responsible officers of the department decided on Saturday to pass Harvey's tea, as there was not sufficient evidence in the reports of the analysts to justify a more rigorous administration of the act.—Melbourne *Argus*.

IMPURE TEAS.

About a month ago (23rd April) the ship "Amalfi" arrived from Hamburg by way of London, bringing as part of her cargo 750 half-chests of tea, which were speedily rumoured to be unsound. As Mr. Blundell, the senior tea expert, refused to pass this tea, the services of analytical chemists were called in. Mr. Johnson, the first consulted, gave two rather contradictory reports—first, that the tea was probably mixed with exhausted leaves, and that it was not damaged in any perceptible way; and next, that the tea was a sound tea if the damaged parts were removed. Unable to reconcile these perplexing reports Mr. Langridge called in Mr. Blackett as umpire, and Mr. Blackett reported that only one sample examined had any approach to a fair proportion of soluble ash. "Broken leaves, stalks and small tea *débris* characterized them all. Rotten leaves were found in abundance." Mr. Langridge has very properly adopted Mr. Blackett's report, and forbidden the tea to go into consumption. The result is that it has been purchased by the trade at a half-penny a pound, and will be passed off upon some unwary community! While the morals of the tea selling trade are in this profoundly unsatisfactory state, it is not reassuring to notice that there was great difficulty in procuring a conviction. It is not the law that is in fault, but the regulations framed for carrying out the act that are not sufficiently precise. The Government have the power, under clause 7 of the act, to revise these, and they should certainly do it; or the old legend of "death in the pot" will become appropriate. Probably it was a mistake in the act to let exhausted tea be given back to the importers for re-shipment. We ought to aim at protecting our neighbours as well as ourselves; and, indeed, for that matter, we have no security that some of this tea may not find its way to Warrnambool, or from Albury back again into Victoria.

A further shipment of common low congou teas having come forward by the steamer "Potosi," consigned on shipper's account to the care of Messrs. Dalgety, Blackwood and Co., that firm have addressed letters to the Commissioner of Customs and to the chairman of the board of health, calling their attention to the fact, and requesting that the teas may be analyzed and examined prior to their being offered for sale in the market. The Central Board of Health has sent on the samples to Mr. Cosmo Newbery for examination and analysis. It need hardly be said that if every firm to whom low class teas are sent would adopt the highly creditable example sent by Messrs. Dalgety, Blackwood and Co., none of those unpleasant contradictions which have figured in the press in connection with challenged teas would have been possible.—Melbourne *Age*, May 24th.

THE AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

A recent report of this Society is not encouraging as some of the previous ones. The fact is reiterated, that, while education is rapidly spreading throughout India, the large body of intelligent Hindus and Muhammadans have not, with very few exceptions, shown that interest in the proceedings of the Society which might naturally be expected from a class who would derive the most benefit. The report alludes to the efforts made to reach the large number of native noblemen and wealthy influential landed proprietors to join. It is shown that there were eighty of them addressed by circular letters, and that out of that number three only responded favorably. Might not the Agricultural Society here take a lesson from this? The President in his opening speech, animadverted to this matter in the following terms: —

Surprise only at such a result does not convey my feeling, which is also one of great regret that such indifference characterizes those who should be foremost in fostering a Society whose aim and object are the furtherance of Landholders' interests, in the improvement of their estates, by a higher and better cultivation of their land, by the use of well selected seeds, and as a natural result, a better and larger yield of crops, and a richer harvest to themselves and to their tenants.

It is doubly disappointing when we think that among such gentlemen there is no lack of leisure, means and ability, and doubtless in many cases, the taste and application needful to devote to such subjects with successful results; and although I am at a loss to understand such apathy, I still look to that wealthy community with a feeling of confidence that, amongst their fixed resident ranks, many may be yet influenced to join us and take an active part in the great and good work initiated and prosecuted with zeal by a few, whose good example should be followed, for they have comparatively but a passing interest in this country, whilst those to whom I allude are in their native land, and with every inducement to come forward and take an active part.

This is the more necessary, for socially, a great change has taken place. The European has become more than ever a bird of passage than formerly. With some exceptions, men are less public spirited and have less time at their disposal. The battle of life is greater, competition is keen, and they have less time to give for the benefit of public Institutions but independently of these facts there is certainly much less public spirit generally, and not that inclination to devote a portion of what is taken from the country for the benefit of the country. This I think, hold good with few exceptions, among the higher classes of the official community, who draw so largely from the State. The more rapid communication with Europe has no doubt greatly contributed to this state of things. In former years a young man entering the service of Government commenced life under the impression that he would probably have to work for a certain length of time in the country undisturbed, and that he should give a portion of such time independently of official work, towards the benefit of those among whom his lot was cast. This feeling was shared by many military men in civil and political employ, as well as by civilians generally. Now the object appears to be to endeavour to accumulate wealth and to retire on as early a date as possible, and all our public Institutions suffer more or less from this state of things; hence the greater necessity for the native wealthy landed proprietors and others to come forward and take their place and stand in our ranks, and become interested in such work as would redound to their own credit, and whilst forwarding their own interests they would benefit their country at large.

REPORT ON THE ROYAL BOTANIC GARDENS, CALCUTTA, FOR THE YEAR 1883-84.

The following is the Resolution of the Bengal Government on the report on these Gardens for 1883-84 :—

The completion of the general scheme for improvements last year left little to be done in the way of original work. The planting out of the palm-house, the erection of which had been completed during the previous year, was the most noticeable work carried out in the Garden during 1883-84. For this purpose, plants that had outgrown the limits of the former low-roofed conservatories were transplanted, while the interspaces between the larger plants were filled in by lower-growing species of various kinds—*aroids*, *marantas*, *selaginellas* and the like. The palm-house already presents a handsome appearance, and the general effect of it will be greatly enhanced as the plants continue to grow. The steam-pump, which was lately erected to keep the river water in the Garden tanks at a high level throughout the year, has proved a success. These ornamental lakes, besides improving the appearance of the Garden, have also conduced to its healthiness. The distance and inaccessibility of the Garden from Calcutta greatly impair its value as a health and pleasure resort. A service of passenger steamers has recently been established, which call at several points within the port, one of the calling places being the Mattiabrujghat opposite the Garden. Mr. King has suggested that, if a landing stage was erected by Government on the Howrah side of the river, at some places close to the Garden, the steamers might be induced to call there and thereby render it much more accessible to the public. The Lieutenant-Governor would be glad to see this done if it does not involve a large expenditure. A communication on the subject will be addressed to the agents of the steamer service. The economic plants which engaged the Superintendent's attention during the year were the *Sabai grass*, the paper mulberry (*Broussonetia papyrifera*), the *cinnamon* plant yielding the *casia* bark of commerce, and the soy bean. The *Sabai* grass was extensively distributed in various parts of the province, and its suitability as a paper fibre has been established beyond doubt. The bark of the paper mulberry, which has an easy and rapid growth, was reported on by a paper-manufacturer, pronounced to be "an admirable paper material. Dr. King believes that the plant is capable of producing one of the very best paper fibres known—a fibre at once strong and fine, and requiring very little bleach. Experience has shown that the plant grows as well in the drier climate of Durbhunga as in the lower parts of Bengal; and with a view of extending the cultivation of the tree, Dr. King is having a large number of plants prepared for issue and for planting out in vacant spots along the Garden boundary. A further consignment of the *cinnamon* plant was received from Hongkong during the year. The plants, though healthy, are quite young; and as they seem to grow slowly, it will be sometime before their suitability to the soil of Bengal can be ascertained. The Soy bean, of which Dr. King had arranged for a supply from Japan, was distributed during the year among planters and others for experimental cultivation. The result, as was anticipated, has been a failure. The experiment of utilizing the ornamental lakes in the Garden as a breeding ground for Gourami fish has also proved a failure. One of these lakes was stocked with a quantity of this fish, which had been supplied by the Hon'ble H. S. Thomas of the Madras Civil Service; but on the lake being dragged some months after, not a single fish could be found. The Superintendent, however, proposes to make a further trial. Owing to the insufficient accommodation afforded by the old herbarium, it had not been possible to arrange and name a large collection of dried plants received during the past few years; but since the completion of the new building, this work has made considerable progress under Mr. Brace's supervision. A beginning was also made in classifying the large number of botanical pamphlets which the Garden library contains. Very valuable contributions were received in the herbarium during the year from the Royal Garden

at Kew, and from Government officers and other gentlemen both in India and other countries. Among the chief contributors were Mr. Kunstler, Mr. Gamble, Mr. Talbot, Dr. Schlich, Mr. Duthie, Dr. Trimen, Mr. Levinge, Mr. Ford, Dr. Cooke, Mr. Hallett, Mr. Maries, Mr. Clarke, Mr. Woodrow, Mr. Hildebrand and Dr. Hay. The interchange of seeds and plants went on actively during the year. Twenty-three thousand eight hundred and nine living plants and 3,716 packets of seeds were distributed, the principal recipients being, as usual, Station Committees, Cantonment Magistrates, and Superintendents, of hospitals and jails. A considerable number of plants was also sent to the International Exhibition in Calcutta. On the other hand, 9,179 plants and 1,038 packets of seeds were presented to the Garden by various contributors. The receipts from the sale of surplus plants amounted to R1,345-11-9, while the whole of the budget allotment of R70,350 was spent For the third year in succession, the Lloyd Botanical Garden at Darjeeling suffered from the ravages of the cockchafer grub. Specimens of this grub and of the beetle into which it develops have been sent to a specialist in London for identification and report but no answer has yet been received. Dr. King's proposal to suspend all distribution of living plants from the Garden in case the grub shows itself again this year, commends itself to the Lieutenant-Governor. A similar grub, it is stated, has proved very destructive in Ceylon to coffee planting in *patana* or grass land. Fortunately the Darjeeling grub has not as yet displayed any partiality for tea. The Lieutenant-Governor desires to acknowledge the excellent work done by Dr. King and his subordinates during the past year.—*Madras Weekly Mail* June 14th.

THE GLENDALE TEA ESTATE, COONOOR.

Mr. Thomas Stanes, so well-known on the Neilgherries, having invited a large party of friends to spend a day at "Glendale," I was fortunate enough to make one of the party which assembled there on Friday last (16th June.) Leaving Coonoor about 9 a.m., we drove some two miles down the New Ghaut road and then turned sharp off to the right in the direction of Katari. After a hilly drive of a mile and a half we reached the foot of a small, but somewhat precipitous hill, on which stands the "Glendale" Tea factory and the manager's (Mr. Brown's) bungalow. On arrival we received a hearty welcome from Mr. Stanes, and plunged at once into the mysteries of the preparation of the tea leaf for the market. On the "Glendale" estate there are three classes of tea trees, the China, the Assam, and a Hybrid. Of these the China bush is grown from seed, imported some years ago by Government. The Assam tree is by far the best producer. It is found at "Glendale" that this tree produces one pound of leaves annually or twice as much as the China bush. To make the best kinds of tea two leaves and a bud are plucked off a succulent green shoot, called the "flush." When the coolie women (chiefly from the Salem and Coimbatore districts) have filled their baskets with the leaves, they cover them up to protect them from the rays of the sun, and bring them into the factory twice a day. As soon as the women arrive the contents of each basket are carefully weighed. This over, the leaves are subjected to what may be called the first process—that of "withering." There is a special room called the "withering house." In this the leaves are placed on shelves until they are withered, or limp. This process is necessary to prevent them from breaking when subjected to the next process, that of rolling. To the rolling room we were in due course taken. Here a Jackson's patent tea rolling machine, driven by a turbine, was in full swing. This machine has a very peculiar motion, best described perhaps as that of the human arm in a bent position drawn rapidly and constantly towards the body. Before the introduction of this machine the leaves used to be rolled by hand on tables, apparently not at all a clean process. By this one machine the work which it formerly took eight men to do is accomplished in far less time. The main object of the rolling is to express the juice from, and as the same time to curl the leaf. The juice must not be lost, and is taken up again by the leaves as the rolling process goes on. The next process is that of fermentation, which requires to be watched very carefully. The leaves, when taken out of the roller, are laid on shelves under blankets, and allowed to ferment for from 3 to 8 hours, according to atmospheric and other conditions. After this they are dried by artificial heat. On "Glendale" this is done by a Kinmond's patent drying machine, by means of a hot air draught, which is an immense improvement upon the old system, and a saving of some 90 per cent of fuel. With the drying of the leaves the manufacture is completed. It only now remains to sort the various kinds of tea, and to garble out any red or imperfect leaves. On the sizing, which is done by a machine, depends the name and the quality of tea. Leaving the drying and sizing room at "Glendale" the visitor is conducted to the packing room and store. Here, as indeed in all the other rooms, one is struck by the neatness and cleanliness of the operations. Considerable quantities of tea are to be found in this room ready for the market, stored in large bins. Under the visitor's eye the whole process of packing is carried on. Here are to be found the tea for which "Glendale" is so famous, Orange Pekoe (at R1·4 0 per lb., on the estate,) Flowery Pekoe (at R1 2-0 per lb.,) Pekoe souchong (at 14 as.,) Broken Pekoe (at 14 as.,) and Congo (at 10 as.) Of these teas Broken Pekoe at 14 as. a lb. commands a very large sale. It should be noted that the above prices are those on the estate. Altogether I have seldom spent a pleasanter or more profitable day than in viewing the "Glendale" tea estate and factory. Mr. Stanes did not fail to show his guests his usual hospitality, nor did they fail to appreciate it.—*Madras Mail.*

DR. SCHOMBURGK, the well-known botanist of South Australia, speaks most highly of the *Marsilea macropus*, or, as it is termed by the natives, the nardoo, which is a plant found to exist abundantly in the interior of that colony, possesses valuable nutritious qualities, and is capable of withstanding the effects of the severest drought. —*Australasian.*

TIMBER IN TEXAS.—As an illustration of the extent of the timber trade in North America the following extract from a recent report from Texas will be of interest:—Notwithstanding the fact that the greater proportion of the State consists of immense prairie, Texas possesses the largest area of woodlands of any State in the Union. The timbered country is situated in Eastern Texas; and, according to the Forestry Report, in 1880 there were 63,000,000,000 feet of standing Pine, worth, on the average at the mills if sawn up into planks, 12 dols. per 1,000 feet. Besides Pine there are large quantities of Cypress timber, both red and white, from which roofing shingles are made. At Beaumont these mills turn out 250,000 daily, and at Orange six shingle mills made during the year 1881 66,000,000. Of Cypress shingles Bois d' Arc is very abundant in some counties, and for posts is unsurpassed, as it will last for years in the ground without rotting. It is also used for carriage and waggon spokes, and is also coming into use for paving streets. It does not appear what the botanical name of the Bois d'Arc is. The report from which the foregoing is taken concludes by saying that the vast territory of Texas, covering an area one-third larger than either France or Germany, with its divers interests and resources, offers an unlimited field of enterprise for the capatalist, and equal advantages in other ways to persons of small means, to practical farmers with capital enough to make a start, and to the mechanic. —*Gardeners' Chronicle.*

Correspondence.

To the Editor of the Ceylon Observer.

QUESTIONS ON VEGETABLE LIFE.

23rd May 1884.

DEAR SIR,—Will you kindly allow me to make use of your widely-read paper to obtain answers to several questions that have lately been puzzling me?

1. *Ground-nuts.*—How are the pods formed underground? I have several of these plants which I have been carefully watching day by day, marking each blossom as it appears and dies off. None of these blossoms appear to leave any seed-vessel; both flower and flower stalk wither away: but after a few days, from the same joint from which the flower sprung appears a small white or reddish point, which grows in length and has the appearance of an aërial rootlet. This root (or fruit-stalk?) is armed with a hard sheath and pushes its way into the soil. I have frequently examined it in section, with a pocket lens, but can find no sign of an embryo seed or structure of fruit. Yet it is on these underground stalks that the fruit afterwards appears.

2. *Pineapples.*—What is the reason that the core of my pineapples frequently splits from the base to about the centre where the fissure enlarges laterally and is filled with a watery fluid? I used to blame the excessive rain, but the recent three months' drought has in no wise remedied the evil, although the plants themselves were almost dried up. Have either wine or sugar ever been manufactured from the juice of the pineapple? ["Pineapple rum" is famous.—ED.]

3. How may white-ants be destroyed in a flower and vegetable garden? They find their way to the roots of any plants that take their fancy, and eat off the tender bark or the stock and rootlets, soon killing the plant. I find them particularly partial to plants of the potato family—also sunflower (*Helianthus*) and everlastings (*Helichrysum*), I have tried phenyle oil with little success as it does not appear to kill the ants but is fatal to the plants, although used as per directions on the bottle. I notice that several of the large species of the true ants prey upon the termites whenever they find them in the open.—Yours truly,

AMATEUR.

BEES AND THE COFFEE BLOSSOM.

Uva, 26th May 1884.

DEAR SIR,—The absence of bees during the coffee-blossoming seasons has been commented upon for some years past. I observe that they have come back in force this season, and would be glad to know if this has been the case in other districts? Can it be that the seasons are changing or is it that the bees are now finding their accustomed food?—Yours truly,

MORE LIGHT.

[Worthy of "Swaddy" 's attention.—ED.]

CINCHONA HARVESTING.

27th May 1884.

DEAR SIR,—I venture to offer a few remarks on this subject, consequent on my reading the report of the sub-committee on cinchona, appointed by the Dimbula P. A. I must begin by requesting your readers not to consider the tables given below as what cinchona may yield per acre, but solely as a means of comparing the merits of the shaving and coppicing processes. It is necessary for this purpose to explain first that I make the following assumptions:—I begin with 1,200 trees (not an acre or acres) and I assume that they will die off in about the proportions given (I need not say that in unsuitable land and climate the proportions will be much greater); that the original bark analyses 1·80 sulphate of quinine and the renewed gives 3·50 per cent; that the cost of harvesting, covering and delivering is 12 cents per dry lb., and the price per unit stands at 25 cents. Further, I assume that succirubra is the tree planted.

Table A.—Shaving.

Number of trees.	Age. Years full.	Analysis. lb.	Number of lb. dry bark at each annual harvesting. lb.	Proportional amount of quinine in lb. lb.	Cost of harvesting, etc., delivered in Colombo at 12 cents per dry lb. R.	Value in Colombo per dry lb. at 25 cents per unit—branch=7 cents per lb. R.
1,200	3	1·80 per cent	300	5·40	36·00	135·00*a*
1,000	4	3·50 ,,	333	11·65	39·96	291.37*a*
850	5	...	283	9·90	33·96	247·62*a*
800	6	...	400	14·00	48·00	359·00*a*
700	7	...	420	14 70	50·40	367·50*a*
650	8	...	433	15·15	51·96	378·87*a*
600	9	...	450	15·75	54·00	393·75*a*
550	10	...	412	14·42	49·44	360·50*a*
	Totals	...	3,031	100·97	363·72	2,524·61

Table B.—Shaving and coppice at end of 10th year.

		lb.	lb.	R.	R.
Totals as above at end of 9 yrs.		2,619	86·55	314·28	2,164·11*a*
550...10 years (coppiced)...	3·50 rend.	420	14·70	33·60	367·50*b*
	1·60 origl. branch	200	3·20	16·00	80·00*b*
		300	...	18·00	21·00*b*
		3,539	104·45	381·88	2,632·61

Table C.—Two shaves and coppicing.

	Yrs. full.	lb.	lb.	lb.	R.	R.
1,200	3	1·80 p. c.	300	5·40	36·00	135·00
1,000	4	3·50 ,,	333	11·65	39·96	291·37
850	5	3·50 ren'd	800	28·00	64·00	700·00*c*
(coppiced and leave for 4 yrs.)		1·60 origl. branch	250	4·00	20·00	100·00*c*
			450	—	27·00	31·50*c*
800	9	1·80	266	4·79	31·92	119·70
780	10	3·50 ren'd	730	25·50	58·40	638·75*d*
(coppiced)		1·60 origl. branch	200	3·20	16·00	80·00*d*
			400	—	24·00	28·00*d*
			3,729	82·59	317·28	2,124·32

It must be evident that the most important point is the quantity of quinine produced in a given time, as upon that hangs the value of the bark. From table A it may be seen that at the end of the tenth year 100·97 lb. of quinine is obtained (in the bark) costing about R3·62. From table B (deducting branch bark), 10·45 lb. quinine is got, costing about R3·58, while each table shows a selling price of almost exactly R25 per lb. quinine (in the bark). Therefore, *cæteris paribus*, the system adopted in B is more remunerative than that adopted in A, but very slightly so, and I think that if the branch and original bark to which attention is called in the remarks column were added there would scarcely be any difference between the two systems in point of profits. Turning to table C, we see that 82·59 lb. quinine (in the bark) is obtained at a cost (deducting branch bark) of R3·22 per lb., while the sale price (deducting branch) shows R25 per lb., so that, *cæteris paribus*, this shows a better return during the ten years than the system adopted either in A or B.

If, again, the cost of harvesting &c. be deducted from the sale proceeds, table A, at the end of the tenth year shows a profit of... R2,160·89

table B	R2,250·73
table C	R1,807·04

a To this should be added the value of branch bark from annual prunings, say R75 profit, as well as for some original bark, as the trees are shaved gradually higher and higher, say R250. Bark from dying trees omitted.

b Costing 8 cents to harvest, as there is no covering this time; branch 6 cents.

c Costing 8c as there is no covering; branch at 6c cost, and 7c sale.

d Cost 8c as there is no covering; branch at 6c, and 7c sale.

so that, taking into consideration only those factors which I have assumed at the outset, and the heads of the various columns, the system of shaving, or shaving with a coppice at the end of 10 years has a decided "pull" over the system recommended by the D. P. A. Committee. Of course it is uncertain, meantime, whether the trees would stand so many shavings; but they have been shaved seven times at least, in actual practice. In any case, it seems to be more profitable to go on shaving every 10 or 12 months, until the trees show signs of inability to renew the bark and then coppice. If the trees were not shaved till four years old, it would make very little proportional difference in the tables, as the shaving in the third year is the same in all.—Yours faithfully, A. M. W.

GERMINATING TEA SEED, ETC.

DEAR SIR,—Could you or any of your correspondents give me the following information? What is the quickest and best way to germinate *tea* seed before planting in nursery, and what distance apart in the beds should the seeds be planted to ensure good strong plants? ENQUIRER.

[Our correspondent, if he had read carefully, would have observed in our columns recently a statement that tea seed germinated splendidly in damp sawdust. As to distance in tea nurseries, we suppose three inches is a common distance and a fairly good one, inferior plants being rejected. In situations where drought is feared at planting time and where the use of transplanters is contemplated to take up a large ball of earth with each plant, perhaps four to six inches might be allowed. But nurseries with seeds six inches apart would be very expensive. Perhaps experienced planters may answer this question.—ED.]

CINCHONA CULTIVATION.

SIR,—We have just read the very lucid and instructive report of the Sub-Committee of the Dimbula Planters' Association on cinchona cultivation, but may we ask for fuller information on, and explanations of, the following somewhat contradictory and confusing statements:—

In paragraph No. 3 of the Committee's report, they say:—"By the majority, no difference has been noticed between trees raised from foreign and local seed; but by some *that* have tried *it*, *they* are considered to be less liable to canker." Who, may we enquire, are considered to be less liable to canker? The men who have tried it! ‡

In paragraph No. 4—"Harvesting:—* * * The majority are of opinion that shaving checks the growth of the tree, especially *after five years old*, and in some cases it is said to kill the tree." They also say:—"There is a good deal of evidence in favour of stopping shaving when the tree is *five years old*." Further on they have it:—"The majority are of opinion that trees will renew bark well, if shaved *after five and half years old*." How are we to reconcile these conflicting statements?

In appendix, section 2—Planting—in answer to question 1, "Have you found plants, stumps or cuttings to answer best?" Nos. 15 and 2 say: "*Plants from cuttings*;" and No. 4 says: "*Plants cutting in doubtful weather*." Can you explain what is meant?

Section 3—Cultivation.

Question 3.—"What style of lopping do you find to answer best?"

No. 11 answers:—"*Two branches twice* a year." How does he do it?

Section 4—Harvesting.

Question 4.—"What material *you covered with*, if any?" (A strange question!)

No. 4 answers:—"Dried patana." What *is* this, and how is it applied? Is it liquid or solid? [Clearly patana grass was intended.—ED.]

Question 12.—"What time of the year you consider best for shaving?"

No. 3 replies:—"Light shaving weather." Never heard of it before! What is it like?

Question No. 14.—"Have your trees, *when covered*, rotted *after shaving*?" (I suppose this question should be:—"Have your trees, when covered after shaving, rotted?" The original question is queer!)

No. 3 answers:—"Not covering in weather." What *can* one make of this?

Section 5—Coppicing.

Question 8.—"What in your experience is the proportion of bark obtained by coppicing as opposed to shaving, &c.?"

No. 15 answers:—"Sixteen times as much." Oh! Oh!!

The italics are our own: there are several other discrepancies in this report which we would like explained, but we fear we should take up too much of your valuable space if we noted them all.

Trusting you can give us information on the above quotations, we are, yours truly, UVA.

[Our hypercritical and jocative correspondent has simply succeeded in showing that a report containing much valuable information is not a model of faultless composition. Some of his conundrums beat "facts and fancies" hollow. The information alluded to in a private note will be very welcome to us.—ED.]

CINCHONA BARK: QUALITY AND PRICES.

DEAR SIR,—You give us from time to time in your paper a quotation of the prices of cinchona bark per unit, but can you or any of your readers enlighten us as to how the prices per lb. of bark have decreased in the local market?

I hold a considerable number of certificates of analysis by Mr. Symons extending over more than two years, and within that short time I see a gradual decrease in the percentage of quinine, and my barks do not now yield one-half what they did some time ago.

Why don't you give us the names of the firms who openly buy cinchona bark in Colombo? I do not hold it just for the same people to buy as well as sell such an article as cinchona bark. It short, let your readers know who make it their business to sell their constituents' stuff, and who are buyers only.

SHAVINGS.

[Our correspondent asks us to give information which is beyond our reach. At public sales, and with competition, bark ought surely to sell at its value. That value fell greatly, but is now recovering with the break-up of the "ring" and the consequent large sales of cuprea bark.—ED.]

BEES ON COFFEE ESTATES.

DEAR SIR,—I do not think that the apparent increase in the number of bees can be ascribed to either of the reasons put forward interrogatively by "More Light," but their appearance is due to the natural course of events, for, as each year shows a decline in the extent of coffee cultivation, proportionately will an apparent increasement in the number of bees visiting the remainder be noticeable. As coffee only blossoms at periodical intervals, the existence and numbers of those valuable insects cannot be dependent upon its acreage, but rather upon the permanence of those different wild flowers that blossom in succession throughout the year. Naturally they are to a great extent influenced by the extension of the coffee industry, since the destruction of their habitations and feeding-grounds to make room for cultivation must necessarily cause a considerable

reduction in the swarms, and is serious for such reduction is permanent. As the number of young clearings increased, a smaller number of bees had to search over the same surface as before for means of subsistence; but with their feeding-ground reduced in area, whilst our requisition for their services was annually increased, to have performed their functions with the desired ratio of benefit, each year their numbers should have increased to an enormous extent, being the reverse of what has occurred. Assuming that a bee could search over ten acres of forest in a day, when under coffee and a good blossom out, a quarter of an acre would be an excessive day's work, that is, 40 times the previous number of bees would be required on those occasions; these figures are of course suppositions. Now the truth is that they have decreased in numbers instead of increased, as they have actually a smaller surface from which to obtain nutriment for their subsistence during the year, thus regulating the numbers to be provided for; and as long as the average of unopened land is constant, so long will the average of bee population remain constant. Of late years an extensive acreage on which coffee was originally planted has been put under other products, the coffee being removed, and many estates have been entirely abandoned; by these means during the blossoming season a very considerable reduction has been effected in the surface extent of coffee for the bees to visit, and consequently though their actual numbers remain the same, they appear in greater force since their field of action is contracted. The following example will explain my meaning: suppose an isolated district, which includes 500 acres of coffee, is capable of supporting ten colonies of bees, and that this area under coffee is reduced one-half, then during the succeeding blossom there will be double the number of bees visiting the 250 acres still existing; they will present the appearance of an increase in their numbers, whilst really they still remain the same in point of multitude. From the "Directory" I glean the following figures:—80,950 acres were in cultivation in 1856; these figures were increased to 176,467 in 1869, and to 272,243 in 1877; this was coffee alone, and the regular available feeding surface was reduced by this acreage; therefore a corresponding reduction must have ensued in the quantity of bees. Assuming that this quantity has remained without material alteration, as so small an area of land has been opened since then, we can naturally expect, that, if the coffee acreage is largely curtailed, a proportionate number of bees will be rendered available to work through the existing coffee, and therefore will appear to have increased. In 1884, 153,600 acres appear to be kept in coffee, thus showing a difference of 118,643 acres or nearly one-half less coffee to visit, and consequently their numbers will appear doubled. At the same time there is the probability that the bees may have received reinforcement through food supplies being obtainable in greater quantities by the total abandonment of 53,540 acres, and a larger number could thus be supported.—Yours faithfully,

SWADDY.

JACKSON'S TEA DRIER.

DEAR SIR,—In the *T. A.* of May 1st I remark there is a description of "Jackson's New Tea Drier" from the *Home and Colonial Mail*, which, though a very good paper, does not appear to be in this case particularly lucid in its description of the "New Drier." We must only hope that Messrs. John Walker & Co. will make it more plain to the ordinary or "garden" planter. The *Home and Colonial Mail* mentions the fact that elder leaves (with which the machine was tried) after being rolled in an Excelsior *are not* tea leaves. Will you, Mr. Editor, being a person who knows a tea leaf, corroborate this statement? The *H. and C. Mail* goes on to say that "the *tea* (*tea* before it is even put into the drier?) is thrown into a hopper (I know from experience that hoppers go well with early tea) and falls on to an endless band consisting of metal plates (this sounds rather strange) and is evenly distributed over the band by a kicker (surely they can't mean that horse-power is used); the first endless band drops the tea on to another longer and lower endless band, which in its turn carries it to another longer and lower endless band." One would think, that, with all these endless bands, the tea, like "Tennyson's brook," would go on for ever. The elder leaves, it says, were discharged thoroughly dried and crisp in 15 minutes. (I would like to discharge my present boy under the same conditions.) Thermometers and "speed pulleys" are placed everywhere, and so, it says, the speed and heat are under perfect control. The name and price have not yet been decided upon. "What 's in a name? That which we call a rose," etc., etc. What's in a price? Messrs. Thompson will get lots of orders without mentioning the price.

The first machine is going to a place sounding very like Connemara—let us hope it will not be "boycotted." One fact is mentioned which may perhaps explain everything, and that is, that Messrs. Marshall & Co. received the visitors who attended the trial with the hospitality and courtesy for which they have earned a well-merited reputation. I am inclined to think that the correspondent of the *H. and C. Mail* partook of that hospitality.—I remain, your obedient servant,

O. H. THAT.

TEA SEEDS AND PLANTS AND THE POSSIBILITY OF GOING AHEAD TOO FAST WITH THE TEA ENTERPRIZE.

DEAR SIR,—Day after day your advertisement column shows a falling-off in the price of tea plants, and day by day the lower prices of seed will induce people to put in nurseries themselves rather than pay the exorbitant prices charged in some cases by nursery-holders.

If a fair basis of cost of plants be the price of seed and the expense of rearing with, say, a reasonable margin for land and trouble, then it is at once evident that anything over, say, R5 per 1,000 for tea-plants from Ceylon seed is unreasonable. Unlike cinchona, which so often refused to germinate even in the palatial erections one used to prepare for its reception, or which when germinated required so much attention in watering, poochy-mixture applying, &c., too often rewarded by the so-called "canker" patches occupying the whole beds to the discomfort of both plants and nursery-men. Unlike cinchona, I repeat, which in many soils was so hopeless that the operation of putting in a nursery resolved itself into throwing away money, *fresh* tea seed will grow into plants anywhere it is put in. It may be a little averse to some kinds of gravel; it does not like quartz in most instances, and would not, I fancy, do well on paving stones; with these few exceptions, I know no soil or locality where it would not flourish. It comes up just as well without covering of any sort; it needs little or no watering. I have had really fine Assam hybrid (Amluckie seed) uncovered through four hot months without losing a plant (true, the seed was very fine, large stuff which invariably gives you the best and hardiest plant, and some inferior Ceylon alongside suffered considerably), but in any case the watering necessary for tea in a well situated nursery is trifling. Exposed ridges I have seen it doing well on; patana swamps it seems to like, as good plants as one could wish for. I have grown on the edge of an estate road, and to sum up, wherever good seed

is put in, there you are sure of plants. I have no wish to prejudice the sale which so many nurserymen are now doing well on. In fact, two years ago I got R30 per thousand for tea plants, and my conscience in no way interfered with my accepting this figure (which at the time I thought rather too little); but what I wish to make clear is that tea plants are now, or will be shortly, within the reach of everybody, and that consequently a tremendous increase in the planted acreage will be the result. Tea will be planted wherever men have the land and money, and this tea will in most cases not be of the good jats which we shall surely require when we compete with India. Low prices will always fall heavier on the men who have inferior kinds, and in many cases estates which would not even *grow* coffee trees will be expected to make their owners' fortune in tea. The result will be that in a few years Ceylon tea will lose its present high character, and this, reoperating on the people who have in some measure caused it, will entail widespread ruin and disaster. Now, sir, is it not time to utter words of well-meant warning? I am no pessimist, and have great faith in the bright future in store for tea where judiciously planted, and with high-class plants; but anyone can see much trouble looming in the distance for those who recklessly shove plants of any sort into any soil in any way, so as to be able to call a considerable acreage "tea." I pray that they may not bring down others with them. Would it be an impossibility to procure through the agency of the Central Association the results of the cultivation of, say, ten tea estates in various localities, *i.e.*, expenditure and nett returns, number of coolies per acre and cost of machinery, with range of prices to show increase or decrease during last two or three years. Something of the sort should be certainly done both for the information of the planters and for the necessary consideration of the labour question which (if, as I have heard stated, tea estates require in full plucking three coolies per acre without contractors) will soon prove a terrible drawback to the enterprize.—I am, dear sir, yours, &c., A. B. C.

GERMINATION OF CEARÁ RUBBER SEEDS.

Mercara, North Coorg, Madras, 2nd June 1884.

DEAR SIR,—I have read your paper with great interest, and, though I have received much valuable information from it, I have never hitherto been in a position to add to its stores of knowledge. I have lately been making experiments in the growth of Ceará rubber. It seemed to me that the tedious operation of filing each seed might be done away with.

I am glad to be able to inform you that my experiments have been at last crowned with success. By my method the attacks of ants need not be guarded against, as it seems only to be liable to such attacks when filed. The rats seem also to leave it alone which is another great thing. In fact, by this system, no plants need be lost at all with a little care. I will now proceed to explain what should be done.

Put into a shallow box (a brandy case will do) about two to three inches of fresh horse-dung, first removing carefully any straws, &c. Then having spread it out smoothly, lay the seed rather thickly on it; after this cover the seed with the same number of inches of the same material. Nothing more need then be done but to take care that the dung be kept damp. The seed germinates in a week to ten days, and shortly afterwards shows above the manure. It must then be transplanted into a nursery or into baskets filled with earth as the dung will not be sufficient alone.

I hope the above will be of use to some brother-planter, and that, when others try it, they may be able to improve upon it. I have only lately made this discovery and have no doubt that two heads or more will prove better than one.—I beg to remain, dear sir, yours faithfully,

J. B. FERGUSON.

RICE CULTURE BY MEANS OF MANURE.

SIR,—Mr. Werakody's statement (p. 875, Vol. III.) shows that the yield of rice is increased by the use of fish refuse as manure, but it would have been more complete and instructive to his fellow-cultivators, had he mentioned the extent of land over which the manure was used, and the increase in weight or measure of the crop due to the 2 cwt. of fish used. That manure of any kind will more or less benefit paddy is not a thing that needs proof, but the question really to be settled is how many cents worth of paddy can be got from, say 50 cents worth of manure applied to the soil. The way to settle this point is: take two equal extents of the same field; leave the one plot unmanured, but in every other respect treated the same as the manured portion; keep an exact account of the original cost, carriage and application of the manure. When the crop is reaped, weigh or measure the whole crop of the unmanured plot; weigh or measure an exactly equal quantity of the crop of the manured plot. That which remains over, is due to the manure used, and, to make it a paying transaction, should be of sufficient local value to cover the whole cost of the manure and leave an overplus as profit otherwise it will not pay. It is nonsense to say, that rich manure tends to further impoverish land already as poor as it can well be. All organic matter in its decomposition yields more or less plant-food, and, in so far as its composition contains plant-food, it will enrich the soil to that extent. The cultivator has no right to complain of the result of a manure that increases his crop to the extent of paying all costs and leaving a profit. He must not look for permanent improvement from a single application. When the crops have exhausted the manure, of course, the land will be as poor as ever, but he cannot eat his cake and have his cake: if he finds that 50 cents worth of manure will give him an additional 60 cents worth of crop, he will stand in his own light, if he does not repeat the operation as often as he finds it necessary. The fertility of exhausted land can only be restored by putting into it more plant-food than the crops take out of it, and to bring it up to a given standard the applications of manure must be frequent. L.

[Lawes' experiments proved that the effect of stable manure applied to land was evident a score of years subsequently, and there can be little doubt that so in proportion other manures will not only give better crops but absolutely add to the fertility of the soil.—ED.]

CAMPHOR is made in Japan in this way: After a tree is felled to the earth it is cut up into chips, which are laid in a tub on a large iron post partially filled with water and placed over a slow fire. Through holes in the bottom of the tub steam rises slowly, and, heating the chips, generates oil and camphor. Of course the tub with the chips has a closely fitting cover. From this cover a bamboo pipe leads to a succession of other tubs with bamboo connections, and the last of these tubs is divided into two compartments, one above the other—the dividing floor being perforated with small holes to allow the water and oil to pass to a lower compartment. The upper compartment is supplied with a straw layer, which catches and holds the camphor in crystal in deposit as it passes to the cooling process. The camphor is then separated from the straw, packed in wooden tubs and is ready for the market. The oil is used by the natives for illuminating and other purposes.—*Leader.*

THE GAMBOGE TREE.

TO THE EDITOR OF THE "MADRAS MAIL."

SIR,—In reply to your correspondent "D St. R. S." wishing to know if the *Coorkapooli* (*Jaga Dulcis*) is identical with the gamboge-producing tree, and the mode of collecting sap, &c., allow me to state that the Coorkapooli is quite a different tree to the gamboge-producer, and belongs to the natural order *Leguminosæ*, whereas the gamboge belongs to the natural order *Clusiaceæ*. Gamboge is obtained from several plants in Southern Asia, one of which is the *Garcinea pictorea* which is found growing in the mountain lands of Wynaad, Mysore and Ceylon. Attempts to cultivate it in the lowcountry have failed. The method of collecting the gamboge is by barking the trees in patches of a hand breadth each at early morn, and the gamboge runs out in a semi-fluid state, and concretes about the wound, when it is scraped off by the collectors the next morning. —JOHN SHORTT, Yercaud.

WARAS.

BY W. T. THISELTON DYER, C.M.G., F.R.S.

Perhaps I may be allowed to add a few remarks to what is stated about "waras" in Mr. Kirkby's interesting paper in the last number of the *Pharmaceutical Journal*. The note contained in the inclosed copy of the 'Kew Report' for 1880, p. 50, is, I believe, the origin of the identification of the plant producing the Aden drug with *Flemingia congesta*.*

Professor Flückiger, with whom I had corresponded upon the subject, informed me (July 12, 1881) that though he at first objected to *Flemingia* as the source of "wars" he then thought the statement correct.

As the Kew Museum contained no satisfactory specimens of either African or Arabian "waras" we applied to the Resident at Aden to kindly assist us in procuring samples. These reached England in July of last year. In both cases the "waras" itself agreed microscopically with an authentic sample derived from Professor Flückiger, and had the structure figured by Mr. Kirkby. All three also exhibited the characteristic property of turning first bright red, then black, when carefully heated in small quantity on a glass slip over the flame of a spirit lamp.

The sample of Somali "waras" was mixed with seeds of a dull brown colour mottled with black. These were found to agree precisely with the seeds of *Flemingia rhodocarpa*, Bak., from the Mozambique, which, as mentioned in the 'Kew Report' (*l.c.*), "has its pods covered with a bright red resinous pubescence." A futher scrutiny of the original specimen obtained by Captain Hunter from the neighbourhood of Aden, which is in a rather immature state, led Professor Oliver to the conclusion that this also belonged to *Flemingia rhodocarpa*. I believe that the drug is derived from the young pods and am disposed, therefore, to think that Dr. Dymock is in error in describing it as "the gland of the leaf."

I communicated these further facts to Professor Fluckiger, and he wrote to me, October 4, 1883, "I am very much pleased with your statements and can only say, that I most fully agree with your conclusion as to the identity of the somali 'waras' with my original specimen and also that of the seeds of *Flemingia rhodocarpa* with those met with in the said drug."

In the new 'Official Guide to the Museums of Economic Botany at Kew' (No. 1, p. 45) we accordingly state that "waras . . . . consists of the epidermic glands of the young pods of *Flemingia rhodocarpa*, Baker, native of Arabia and East Tropical Africa."

The third variety described by Mr. Kirkby is quite new to me, and I join with him in hoping that some further information about, the plant yielding it will soon be forthcoming.—*Pharmaceutical Journal.*

* The following is the note referred to:—

"*Waras.*—A drug known under this name appears to be exported in considerable quantity from Aden It is used as a substitute for kamala, a well-known Indian product of *Mallotus philippinensis* (*Rottlera tinctoria*, Roxb.) Its origin is quite unknown (*see* Flückiger and Hanbury, 'Pharmacographia,'" pp. 575, 576). At the suggestion of the former, Captain Hunter, Assistant Resident at Aden, obtained specimens of the plant stated to yield waras in Arabia. He has also sent one to Kew with a note stating that it was gathered 'at an elevation of 6000 feet on Jebel Dtbubarah, 60 miles due north of Aden.' The plant sent was immediately identified with a leguminous species, *Flemingia congesta*, Roxb., having of course no affinity with *Mallatus philippinensis*.

"True kamala consists of the epidermal glands detached by brushing from the fruits of the *Mallotus*. Alcohol extracts from it a splendid red colour. The name 'waras' means saffron, and it may be mentioned in support of the notion that a similar substance is yielded in Arabia by perhaps one or more species of *Flemingia*, that dried specimens belonging to this genus stain paper in the herbarium a bright yellow colour when washed over with the alcoholic solution of corrosive sublimate used to protect them from the attacks of insects. *Flemingia rhodocarpa*, Bak., from the Mozambique district has its pods covered with a bright red resinous pubescence.

"In the 'Pharmacographia,' (2nd ed., p. 372), Flückiger and Hanbury state that *Mallotus philippinensis* grows in Abyssinia and Southern Arabia. In a letter, Professor Flückiger doubts whether he and Mr. Hanbury were not mistaken in regard to this. The evidence of specimens in the Kew Herbarium only carries the distribution to the west as far as Scinde. There is nothing improbable in its extending to Arabia, the flora of which is still so imperfectly known."

MANUFACTURE OF RAISINS.

It is said that there are but few localities in the world where this industry is carried out successfully. All our present foreign supplies come from Southern Spain and Italy, which sources have no rival in the word's market. The choice varieties of Grapes from which raisins are made require a very peculiar soil for their proper maturity, and also the conditions of climate where they can be perfectly cured are rare and limited. They must, for perfect results, be cured in the open air, in contact with a dry and heated soil, in an atmosphere void of all dampness, secure from rain and drew, and under the hottest sunshine. Artificial heat gives at best only a very inferior article. From these requirements it is easy to see why raisin production has taken a limited range, and why the vast Grape regions of the country have never attempted it. In Fresno County, California, vineyards are being established on a large scale, and it is believed that in this district will be found all the *desiderata* needed for the production of raisins. The fruit needs only to be cut from the Vine with the utmost care, and deposited in a shallow tray set at its root, and left there to dry for a couple of weeks. It is then turned by placing an empty tray on top and upsetting the whole body, and then is left to dry a week or more longer. The heat of the torrid sun thus dries it completely. The dried bunches are then put by layers into a box termed a "sweat-box," holding about 100 lb., and covered up. Here the drying becomes perfectly equalised. Then the fruit is carefully and tightly-packed in 10 lb. or 20 lb. boxes, interlaid and covered with fine paper, the covers are nailed tightly on, and they are ready for market. This is the plan adopted in California, and the experiment, so far, has proved both successful and satisfactory. Already many thousands of acres have been planted with the peculiar raisin Grape. It is only recently that this industry has been attempted in California, and the workers have as yet had but little time to mature their processes. The Vines are young, and it is held that the raisin Grape gives its best products upon Vines of considerable age.—*Gardeners' Chronicle.*

THE COLONY OF BRITISH HONDURAS: ITS RESOURCES AND PROSPECTS.

BY D. MORRIS, M.A. London: E. Stanford. 1883.

The author was invited by the Government to pay a short visit to the colony of Honduras in order to investigate its flora and economic resources. The result is the account, or rather the report, contained in this work; plants of purely botanical interest being for the most part omitted, but special attention being devoted to the industrial productions of British Honduras.

The name of the colony has been chiefly connected hitherto with the trade of mahogany and logwood; and the

writer endeavours to show that the place offers natural facilities for more extensive commercial enterprise.

It is somewhat discouraging to find that a fair amount of capital is indispensable to the successful colonist; and as £1000 seems the lowest estimate, a new field of energy is offered rather to the experienced cultivator than to a young man seeking to advance his fortunes in an unexplored and rising country.

It appears, however, that British Honduras has a special opening not only for sugar plantations, cacao and coffee, but for the smaller industries connected with fruit and vegetables.

The most interesting plant found wild in the forests is the indiarubber tree, the *Castilloa elastica*.

The original supplies of indiarubber are likely at no distant date to fall short of the demand; and as this tree is most abundant throughout the colony, great hopes may be expected from its cultivation.

The mode of extraction and preparation are detailed at length; and Mr. Morris, adopting the favourable opinion of Mr. Clements Markham, considers that this Central American rubber is well worthy of attention. The authorities of Kew have procured various rubber seeds and plants, and distributed them far and wide for the purpose of establishing them under cultivation; many cannot be easily cultivated under ordinary circumstances. The castilloa tree offers all round the most advantages, as it strikes its roots far into the ground without exhausting the surface soil; it grows with wonderful rapidity, soon forming a handsome shade tree; and lastly it gives a return in rubber within eight or ten years, while most other trees do not mature for some twenty or thirty years.

Amongst the economic plants mentioned are the vanilla, indigo, arnatto and the guaco; the last known to us as a febrifuge and anthelmintic, and possessing a local reputation as a supreme antidote against serpent's bites.

The larger industries, such as the fibre-producing plants, the sugar cane and others, hardly concern the pharmacist, but the description of nutmegs, pimento, cinnamon, cardamoms and spices generally, from an economic point of view will repay perusal.

The system of cash payment, as specially visible in the fruit trade, has given an entirely new impetus to commerce. The planter was formerly in the hands of an agent; now he can choose his own market, and secure immediate returns.

Intending settlers are advised to gain practical experience from an established colonist, before venturing on their own account, and to trust to commercial undertakings, as there are no salaried appointments in British Honduras.

The book is a careful record of the commercial capabilities of the colony, founded upon personal investigation. —*Pharmaceutical Journal*.

EFFECTS OF DIFFERENT MANUAL APPLICATIONS UPON THE GROWTH OF FRUIT TREES.

It is hardly possible, says Prof. Penhallow,* to gain a thorough insight into the cause of growth or of the diseases of plants unless we have first collected accurate data concerning the laws of nutrition and the effect of special food elements in different chemical combinations upon the growth of particular species and varieties; and it is thus certain that we cannot hope to discover the means of correcting or preventing an abnormal condition until such data are obtained.

Plants belonging to the same family necessarily present well-defined physiological peculiarities which are common to all, and to this extent they would require similarity of treatment, but in individual cases we discern a more or less strongly marked departure from these general laws, which requires a different course of treatment for each member of the family. While this is stated to be true in the highest sense between the various genera, it is also true, though perhaps in a less degree, with regard to different species or even varieties.

Considerations of this nature led Professor Penhallow to see the importance of a systematic course of treatment, by means of which the special action of different plant-foods might be noted as affecting different species and varieties of fruits when applied under the ordinary conditions of field cultivation. For this purpose it was decided to establish an orchard, into which should be introduced varieties of fruit trees and Vines for experimental treatment, and it was further designed that the subjects should be selected (1) so as to include at least one of all the larger fruits; (2) on account of the special value of the fruit; (3) from its liability to disease; and (4) on general consideration.

With these guiding ideas in mind, the following trees were selected:—Quinces, Grapes, Peaches, Apples, Pears, Plums, and Cherries.

The manurial applications were arranged as under:—

No. 1. Without manure.

No. 2. Farmyard dung.

No. 3. Chloride of potassium, dissolved bone and kieserite (sulphate of magnesia, 55·6 per cent).

No. 4. Nitrate of potash, dissolved bone, and kieserite.

No. 5. Nitrate of soda, dissolved bone, and kieserite.

No. 6. Sulphate of potash, dissolved bone, and kieserite.

Professor Penhallow says, although the experiments are of such short duration, yet the trees developed some striking differences under the various treatments, which he considered largely due to the direct results of the applications made.

It is first noted, that between the manured and the unmanured trees there was a marked distinction of luxuriance of growth, which was in excess in the former in almost every case; and unquestionably the result of proper food being present in considerable quantity, and available to the plant. Again, as between the trees treated with nitrogenous and purely inorganic manures, the former showed a markedly greater luxuriance of foliage and richer colour. In the case of the trees treated with stable dung, the whole growth in several cases was more luxuriant than in those treated with mineral fertilisers.

With regard to the general effects of manures on vegetation Messrs. Lawes & Gilbert aptly remark that "The general tendency of nitrogenous manures is to favour luxuriant and continuous growth, as distinguished from arrest and consolidation of that already formed; whilst that of mineral manures is to favour consolidation rather than luxuriance. Or, to put it in another way, a characteristic effect of nitrogenous manures is to favour the extension of foliage, and give it a depth of colour, whereas that of mineral manures is to aid stem formation and the production of seed. In fact, a relative excess of nitrogenous supply favours the extended growth of the organs of vegetation, prolongs their development, it may be, until the resources of the plant are exhausted, or the season past. On the other hand, a relative excess of mineral manures may bring on premature ripening. It is the proper adaptation of the two descriptions of supply to the current requirements of the plant, and of the season, that gives both full, properly proportioned, and well-matured growth.

Again, the excessively dark green colour of vegetation is indicative of a high percentage of nitrogen, an abundant formation of chlorophyll, but deficient carbon-assimilation, due to a deficiency of certain mineral constituents relatively to the amount of nitrogen taken up. In fact, there is, so far as the nitrogen available and the chlorophyll formed are concerned, so to speak, potential, but not actual growth. —*Gardeners' Chronicle*.

* Abridged from Professor D. P. Penhallow's report of the experimental farm at Houghton, New York.

OLIVE OIL AND ITS PRODUCTION.

The following particulars with regard to the production of olive oil in Tuscany have been furnished to Mr. Consul Inglis by one of the principal exporters in Leghorn:—

The olive oil produced in Tuscany from the first pressing of the fruit is intended for consumption as an article of food. Hence, great attention is paid both to the culture of the olive tree and the process of making oil.

The olive crop is subject to many vicissitudes, and is an uncertain one. It may be taken as a rule that a good crop does not occur more frequently than once in three years. A prolonged drought in summer may cause the greater part of the small fruit to fall off the trees. A warm and wet autumn will subject the fruit to the ravages of a maggot or worm, which eats its way into it. Fruit thus injured falls to the ground prematurely, and the oil made from it is of

very bad quality, being nauseous in taste and somewhat thick and viscous. Frost following immediately on a fall of snow or sleet, when the trees are still wet, will irretrievably damage the fruit, causing it to shrivel up and greatly diminishing the yield of oil, while the oil itself has a dark colour, and loses its delicate flavour.

The olive tree in Tuscany generally blossoms in April. By November the fruit has attained its full size, though not full maturity, and the olive harvest generally commences then. The fruit, generally speaking, is gathered as it falls to the ground, either from ripeness or in windy weather. In some districts, however, and when the crop is short, the practice is to strip the fruit from the trees early in the season. When there is a full crop the harvest lasts many months, and may not be finished till the end of May, as the fruit does not all ripen simultaneously. Oil made early in the season has a deeper colour, and is distinguished by a fruity flavour, with a certain degree of pungency; while as the season advances it becomes lighter in colour, thinner in body, and milder and sweeter in taste. Oil made towards the close of the harvest in April or May from extremely ripe fruit is of a very pale straw colour, mild and sweet to the taste, though sometimes, if the fruit has remained too long on the trees, it may be slightly rancid. Oil very light in colour is much prized in certain countries, notably France; and hence, if it also possesses good quality, commands a higher price in the Tuscan markets.

The fruit of the olive tree varies just as much in quality as does the grape, according to the species of the tree itself, the nature of the soil, exposure, and climate of the locality where it grows. Some varieties of the olive tree largely grown, because thought to be better suited to the special conditions of some districts, yield a fruit which imparts a bitter taste to the oil made from it; such oil, even when otherwise perfect, ranks as a second rate quality. The highest quality of oil can only be obtained when the fruit is perfectly and uniformly sound, well ripened, gathered as soon as it has dropped from the trees, and crushed immediately with great attention. Should the fruit remain any time on the ground, particularly during wet weather, it deteriorates fast and gets an earthy taste; while if allowed to remain an undue length of time in the garners it heats, begins to decompose, and will yield only bad oil.

The process of making oil is as follows:—The fruit is crushed in a stone mill, generally moved by water power; the pulp is then put into bags made of fibre, and a certain number of these bags, piled one upon another, are placed in a press, most frequently worked by hand; when pressure is applied, the oil flows down into a channel by which it is conveyed to a receptacle or tank. When oil ceases to flow, tepid water is poured upon the bags to carry off oil retained by the bags. The pulp is then removed from the bags, ground again in the mill, then replaced in the bags and pressed a second time. The water used in the process of making oil must be quite pure; the mill, press, bags, and vessels sweet and clean, as the least taint would ruin the quality of the oil produced. The oil which has collected in the tank or receptacle just mentioned is removed day by day, and the water also drained off, as oil would suffer in quality if left in contact with water; the water also, which necessarily contains some oil mingled with it, is sent to a deposit outside, and at some distance from the crushing house, which is called the "Inferno," where it is allowed to accumulate, and the oil which comes to the surface is skimmed off from time to time. It is fit only for manufacturing purposes. After the second pressing the olive-pulp is not yet done with; it is beaten up with water by mechanical agitators moved by water-power, and then the whole discharged into open-air tanks adjoining the crushing-house. There the crushed olive kernels sink to the bottom, are gathered up and sold for fuel, fetching about 12 francs per 1000 kilos., while the *débris* of the pulp is skimmed off the surface of the tank and again pressed in bags, yielding a considerable quantity of inferior oil, called "Olio lavato," or washed oil, which, if freshly made, is even used for food by the poorer classes. The pulp then remaining has still a further use. It is sold for treatment in factories by the sulphide of carbon process, and by this method yields from 7 to 9 per cent of oil; of course suitable only for manufacturing purposes. Only the first two pressings yield oil which ranks as first quality, subject of course to the condition of the fruit being unexceptionable. New oil is allowed to rest awhile in order to get rid of sediment: it is then clarified by passing through clean cotton wool, when it is fit for use.

The highest quality of olive oil for eating purposes should not only be free from the least taint in taste or smell, but possessed of a delicate appetizing flavour. When so many favourable conditions are needed as to growth, maturity and soundness of the fruit, coupled with great attention during the process of oil-making, it is not to be wondered at that by no means all, or even the greater part of the oil produced in the most favoured districts of Tuscany, is of the highest quality. On the contrary, the bulk is inferior and defective. These defective oils are largely dealt in, both for home consumption and export, when price and not quality is the object.

In foreign countries there is always a market for inferior defective olive oil for cooking purposes, etc., provided the price be low. Price and not quality is the object, so much so that when olive oil is dear, cotton-seed, ground-nut and other oils are substituted, which bear the same relation to good olive oil that butterine and similar preparations do to real butter.

The very choicest qualities of pure olive oil are largely shipped from Leghorn to England along with the very lowest qualities, often also adulterated.

The oil put into Florence flasks is of the latter kind. Many years back this was not the case, but now it is a recognized fact that nothing but the lowest quality of oil is put into these flasks; oil utterly unfit for food, and so bad that it is a mystery to what use it is applied in England. Importers in England of oil in these flasks care nothing, however, about quality; cheapness is the only desideratum.

The best quality of Tuscan olive oil is imported in London in casks, bottled there, and bears the name of the importers alone on the label. There is no difficulty in procuring in England the best Tuscan oil, which nothing produced elsewhere can surpass; but consumers who wish to get, and are willingly to pay for the best article, must look to the name and reputation of the importers and the general excellence of all the articles they sell, which is the best guarantee they can have of quality.—*Pharmaceutical Journal.*

PAPER-MAKING MATERIALS.

The attention that has been given of late years to the very important question of the paper supply has resulted in the more general utilisation of many products that were but a few years ago scarcely known. The threatened exhaustion of the Esparto supply went a considerable way to turn the attention of paper-makers to other sources of material, and fresh substances are now frequently brought to notice, the young shoots of the Bamboo being amongst the most recent. The essential for a good paper is a substance that will pulp well, and at the same time possess a fibre sufficiently tenacious to strengthen the paper when finished; thus, the well-known Indian papers made from the tough, fibrous barks of Daphne papyracea and D. cannabina are celebrated for their great strength; and again the Japanese papers made from the inner barks of Broussonetia papyrifera and B. Kæmpferi are sometimes made as thin as gauze, and yet on account of the interlacing fibres they possess considerable strength. Everybody knows how multitudinous and varied are the uses to which the Japanese apply paper. It is then to some of these well-known foreign sources of paper material, the suitability of which is abundantly proved, that we ought to look for some of our future supplies. It is not impossible perhaps to export the material in the form of paper stock or half-stuff, and we might perchance get this either from the Indian Daphne or the Fijian or Japanese Broussonetias; besides which, the plants themselves might be introduced into some of our colonial possessions, and grown for the sake of their fibrous bark; indeed, this would seem to have been already begun by Dr. King in the Botanic Garden, Calcutta; for in his last report on these gardens he says, "The Paper Mulberry (Broussonetia papyrifera) grows wonderfully well, and I am trying to obtain the seed in large quantity from Europe so as to be able to spread its cultivation in India." This, then, would seem to be a new branch of culture well worth consideration and experiment by planters in various parts of the world, for the trees might even be planted on the boundaries of plantations or as shade trees.

The Paper Mulberry grows everywhere in Japan, and is a valuable tree, as furnishing the bast from which a large portion of the Japanese paper is made. The plants are reproduced in quantity by subdividing the roots, and in two or three years are ready to be cut. This work is done in November, and the branches, 7 to 10 feet long, are made up into bundles 3 or 4 feet in length, and steamed, so that the bark is loosened, and can be more readily stripped off. This is washed, dried, and then again soaked in water and scraped with a knife to remove the outer skin, which is used for inferior kinds of paper. The bast, when cleaned, is washed, repeatedly kneaded in clean water and mixed. It is then bleached in the sun until sufficiently white, after which it is boiled in a lye, chiefly of Buckwheat ashes, to remove all gummy matters. The fibres are now readily separated, and are transformed into pulp by beating with wooden mallets. The pulp is mixed in vats, with the necessary quantity of water, to which is added a milky substance prepared from Rice-flour, and a gummy infusion of the bark of Hydrangea paniculata, or of the root of Hibiscus Manihot.

The "couches" on which the paper sheets are produced are made of Bamboo, split into very fine sticks, and united in parallel lines by silk or hemp threads, so as to form a kind of mat. This is laid upon a wooden frame, and the apparatus dipped into the vat, raised, and shaken, so as to spread the pulp evenly, after which the cover is first removed, then the Bamboo couch with the sheet of paper, and in returning the operative lays the sheet upon the others. When a number of sheets have thus been prepared they are pressed, to exclude the water, and afterwards spread out with a brush upon boards and allowed to dry. The sheets are only about 2 feet in length, but sometimes sheets 10 feet long are produced.

On all sides the question of finding substitutes for rags for paper-making is acknowledged to be one of the most important. In Bavaria, according to a recently issued Government report, the paper-makers are directing earnest attention to the discovery of some substitute for rags, "and largely adopting wood, which has not tended to improve the paper, and they still desire to see the export duty re-established, as though the duties on paper under the new tariff may give them the home market, they are desirous of improving their paper and exporting to foreign countries."

Again, in a report from the Consul at Christiania, we read that the produce of wood-pulp increased immensely during 1882, causing prices to fall considerably. Many mills were extended, and several new ones were erected during the year. Some of the mills established in 1881 only commenced working in the beginning of 1882, at a time when the sale of wood-pulp is, as a rule, very limited. The manufacturers tried to force the sale of their produce, and thus large quantities were rather suddenly thrown upon the market, causing a considerable fall in prices. While the consumers in 1881 had to pay from £5 to £5 7s. 6d. per ton for wood-pulp containing 50 per cent of water, delivered free on rail at Christiania, the average price at the close of 1882 only amounted to £3 10s.; and in the summer the best wood-pulp was sold at even £3 5s. per ton. Manufacturers found it difficult to dispose of their large stocks, and as wet wood-pulp could not be well preserved for a longer time, considerable quantities were damaged, and sold as inferior goods at prices varying from £3 to £2 15s. per ton. In consequence of this many mills stopped working until their stock of pulp had sufficiently diminished. In November, 1882, a meeting of manufacturers was held in Christiania, when several subjects connected with the wood-pulp industry were discussed. Thus it was proposed to restrict the produce, but no practical result in that direction was arrived at, except that a committee was elected for a further consideration of the matter. If seems that while in 1875, 8,540,000 tons of wood-pulp were exported, the quantity had risen in 1882 to 59,033,000 tons.

From Drammen the Vice-Consul also reported that the exportation of wood-paper pulp showed a considerable increase. As only a very few mills, however, gave a reasonable profit, the owners were compelled to avoid all possible expense, and therefore a large proportion of the pulp was exported from Drammen direct, instead of *via* Christiania, in order to save the cost of railway carriage between those two places. Since all the paper-pulp mills are situated along the railway line from Drammen up to Konigsberg and Randsfjord, the only reason for exporting the pulp by way of Christiania, and paying heavy railway charges is the convenience which the regular lines of steamers from Christiania to the great places of import afford to shippers. A regular line of steamers from Drammen to a convenient port on the east coast of England ought to pay, especially if a reasonable return freight could be relied on.

In a report from Rome dated at the close of the past year, under the head of paper, it is stated that "this industry, for which considerable hydraulic force is necessary, meets in the province of Rome, with the most favourable auspices, yet there are surprisingly few manufactories; indeed, there are only eighteen moved by a 510 hydraulic horse-power, and employing 347 men, 157 women, and 103 children. The production of paper is a little over 16,000 quintals (31,520 cwt.), though it might be at least 25,000 quintals (49,000 cwt.). The materials used for making it are rags of vegetable texture and straw. A manufactory in Tivoli makes use of asbetos for the production of cardboard. At present the manufacture of paper in Italy exceeds the demand as to quantity, but not as to quality. The newspapers of Rome are printed on paper obtained from manufactories on the river Livi, distance about seventy-five English miles from Rome."

Among the most recent materials applied to paper-making is the fibrous stems of the sugar cane after they have been passed through the mill and the saccharine juice expressed; this, which is known as *bagasse*, has hitherto, in most cases, been used as fuel. In America, however, fuel of all kinds is cheap, so that in Louisiana, for instance, *bagasse* is seldom or never used for burning, and it is a worthless product, some planters indeed not knowing what to do with it. Recent experiments have shown that the hitherto useless *bagasse* contains a fibre that may be utilised for paper-making. A ton of the material will yield about 650 lb. of fibre, while every ton of the latter can be converted into 1,500 lb. of pulp. It has been estimated that each planter who makes 400 hogsheads of sugar might realise no small portion of his yearly expenses by working his *bagasse* and extracting its fibre. A company was formed in New Orleans about a year ago to make paper out of cane fibre. Their numerous experiments have satisfactorily ascertained that paper of an excellent quality can be made from this substance, and that the material is so inexpensive that it can be profitably worked. Certain planters have offered the company all the *bagasse* on their places for from five to ten years gratis. They hope to see this new industry started, so that they will be able to sell their *bagasse* to the factories. Others propose to extract the fibre themselves, for, if once paper factories are established, it will become a marketable product.—JOHN R. JACKSON, Museum, Kew.—*Gardeners' Chronicle.*

LUBRICANTS.*

Lubricants, as is well known, are used for reducing the friction of the moving parts of machinery to the lowest possible degree, thereby preventing undue wear and tear, and, at at the same time, obtaining the greatest possible amount of work from the machinery. Owing to the extensive introduction of mechanical power during the last thirty years, the consumption of lubricants has grown in proportion, until now it is enormous. Lubricants are supplied to us by all the three kingdoms of nature. We derive tallow and train-oil from the animal kingdom; olive oil, rapeseed oil, palm oil, and coco-nut oil from the vegetable kingdoms; resin oil and intermediary oil, so to say, between the vegetable and mineral kingdom.

Tallow is prepared from the fat of cattle and sheep by being heated with water, sometimes with the addition of diluted sulphuric acid or caustic soda, either by the direct application of heat or by hot steam. By this treatment the cellular tissues are destroyed, and the pure fat is separated, which then settles as a layer on the surface. Tallow thus prepared forms, at an ordinary temperature, a yellowish white, pretty hard mass, which melts at a temperature of

* From a paper read by Herr Lux before the Society of German Engineers.

of X 40° C. It contains, if not freed from acids by alkalies, besides the neutral fats, from 1 to 5 per cent of sebacic acid. In examining tallow, care should be taken to ascertain whether it is free from cellular tissues, free from mineral acid, as well as extraneous additions (other fats, sebacic acid, mineral substances, &c.).

Train-oil, prepared from the fat of seals, &c., in a manner similar to tallow, forms, at an ordinary temperature, a liquid of light or dark brown color and of a peculiar odor, solidifying at a temperature of from X 5° to X 15° C. As a rule it contains a large proportion (up to 5 per cent) of sebacic acid. The same care should be observed in examining train-oil, as is recommended in the case of tallow.

Olive oil is obtained by pressure from the fruit of the olive tree, cultivated largely in the South of France and Italy. It forms a beautifully yellow liquid of a peculiar odor, and a mild taste, which begins to get thick at a temperature of X 2° C. The contents of free sebacic acid is very small in the better descriptions; inferior sorts contain about 0·5 to 1 per cent.

Rapeseed oil or rape oil is procured from the seed of the various kinds of Brassica, the seed being crushed in powerful hydraulic presses. The oil thus obtained is a yellowish-brown to brownish-green liquid, of a peculiar odor and a pungent taste, which precipitates the mucilaginous substances of the seed which have passed in pressing only after being kept in store for some time, and becomes clear by this precipitation. But even perfectly clear oils contains mucilage or albumen in chemical solution, and these can only be removed by treatment with chemicals or by heating up to 200° C. The raw oil only cleared by storing was, and is still, used for lubricating bearings, especially railway axles. The purified oil, prepared by removing from the raw oil the mucilaginous and albuminous constituents by sulphuric acid, chloride of zinc, &c., and the free sebacic acid (on the average of 0·4 per cent.) by treating with alkalies, is reserved for lubricating the more delicate portions of machinery and locomotives, steam cylinders, &c. The perfectly purified rape oil, and from which all acid has been eliminated, is of a light yellow color, almost odorless, possesses a specific gravity of from 0·914 to 0·915 at 15° C., solidifies at a few degrees below zero, and melts again at abont X 3° C. In testing rapeseed oil, it must be ascertained whether it possesses the correct specific weight and melting-point, and whether it is free free from mucilage, sebacic and mineral acids.

Palm oil and coconut oil are obtained from the fruit of the oil and coconut palms respectively, imported in large quantities into Europe. The fruit is either crushed in hydraulic presses, or the oil is extracted by means of sulphuret of carbon. The two oils or fats (for at an ordinary temperature they resemble butter) are now used very little for lubricating purposes, but extensively in the manufacture of soap.

Resin oil, gained by distilling the common resin obtained from the residue left in the manufacture of oil of turpentine from turpentine, was formerly used only in the preparation of "carriage grease," mixtures of this oil with colophony, fats, &c. Refined resin oil is now procured by freeing the crude oil by means of alkalies, and subsequent bleaching, the product being a clear semi-liquid of yellow color, possessing but a slight odor, and having a high specific gravity (about 0·970). The oils are never perfectly free from organic acids, most of them containing about one per cent.

The class of mineral oils includes a number of lubricants which have nearly all a common origin with "petroleum." Crude petroleum, as it was first won in large quantities in America (since 1859), consists of an intermixture of many organic substances, which, on account of their exterior similarity to real oils, as well as for simplicity's sake, are called "oils." These oils, which may be distilled without decomposing, differ from each other by their various specific weights, as well as by their various boiling points. For a long time the volatile ingredients only were extracted from crude petroleum, which were used for illuminating purposes, whilst little attention was paid to the heavy oils which remained after distillation. But when those residues grew in quantity, means had to be devised for utilizing them, and it was soon found that they could be used as lubricants. At first the oil was applied in its original form, as left in the alembic, in which it still contains many impurities. But now in most cases, after the more volatile oil used for lighting purposes has been distilled over (at a temperature of from 150° to 350° C.), the lubricating oil is also driven over. The latter is then purified with acids and alkalies, and a product obtained which, in consequence of its impurity, chemical constancy, and other valuable properties, appears very suitable for use as a lubricant.

As the raw mineral oil consists of a large variety of combinations related to one another, and as those combinations, according to a greater or less degree of distillation, &c., may appear in the most various mixtures, it follows that, independent of their greater or less degree of purity, the mineral oils may possess widely varying properties principally of a physical nature. Thus the color of the different mineral oils varies from light yellow to dark brownish red; their specific weights fluctuate between 0·880 and 0·920; their cohesion—their "body," as more generally expressed—shows itself in all grades between the consistency, for instance, of the highly liquid linseed oil, when fresh, and the semi-liquid resin oil, &c. But, however much their physical properties may vary, in their chemical nature mineral oils are closely related to each other. They all consist (of course, only real mineral oils are included) of a mixture of carburetted hydrogen, indifferent organic combinations, which possesses neither acid nor basic properties. They do not decompose either at very low temperatures or at degrees of heat which far exceed those prevailing in the steam cylinders, &c., where they are employed. They do not undergo any change either on contact with the air or with water or steam; they do not attack metals, even the most easily oxydisable, such as potassium or sodium, and are as little changed or decomposed by the metals themselves.

This chemical indifference is the principal advantage possessed by mineral oils over all fat oils, whether they are of vegetable or animal origin. All those fat oils decompose in time on exposure to the air, at high temperatures, on contact with metals or their oxides, and thus destroy, sometimes more quickly, sometimes more slowly the parts of machinery which they are intended to preserve.

Notwithstanding those great excellences which mineral oils have over fat oils, great difficulties were at first experienced in introducing lubrication with the former more generally. Convenience, attachment to custom, and want of intelligence were amongst the obstacles which had to be overcome. Mineral oils were looked upon as entirely unsuitable for lubricating machinery, and fat oils as alone possessing the specific property of a lubricant; apprehensions were raised as to the "easy inflammability" of mineral oils, &c. But the introduction of mineral oils for lubricating purposes was also greatly retarded by the want of sense, and partly also by the want of honesty, on the part of the individual producers and dealers. Properties were claimed for the crude mineral oil only possessed by carefully purified oil; when finally the price of lubricating oil exceeded that of the oil used for burning, part of the latter was left in the lubricant, so that, especially if great pressure took place, it was found unsuitable. Notwithstanding all this, lubrication with mineral oil has, within the short space of the last five years, made such progress that it may justly be called, not only the lubricant of the future, but that of the present day. As the mineral oils on account of their chemical properties are far more valuable than fat oils, and, on the other hand, owing to greater variety physically, they may be adopted more readily for different purposes than fat oils, there is nothing to prevent their general introduction.

It will be gathered from the foregoing that the displacement of fat oils for lubricating machinery by mineral oils is a great technical progress. But the use of mineral oil is a great advantage also from the point of cheapness. The best mineral oils are now only half the price of fat oils. With a suitable construction of the parts to be lubricated and a correct choice of the most suitable lubricating materials, the consumption of mineral oils is not greater; on the contrary, it ought to be less, as with mineral oil no hardening or thickening takes place, and thus there is no loss. Finally in lubricating with mineral oil, the parts oiled are not destroyed, but, on the contrary, preserved; whilst the destruction of machinery parts, such as pivots, regulator valve-rods of locomotives, &c., is only too often a consequence of the use of fat oils.

But the ultimate introduction of lubrication with mineral oils is of importance also from an economical point of view.

Our population is steadily increasing, and the difficulties of gaining a livelihood are growing with it. On the other hand, there is an abundance of suitable material for lubricating with mineral oils. Our food supply would be greatly extended, either directly, by appropriating large quantities of fat and oils for the maintenance of the people, or indirectly, by restoring the areas now used for the cultivation of oil-producing seeds for raising cereals. It is highly necessary in the economy of nations that there should be, not only a division of labor, but also a classification of the work to be done. Let the inferior materials, as far as they can, be used for inferior objects, whilst the more valuable products are reserved for a higher purpose.—*Independent Journal.*

INDIA:—CROP AND WEATHER REPORT.

FOR THE WEEK ENDING THE 11TH JUNE 1884.

GENERAL REMARKS.—Rain has fallen more or less generally in the Madras Presidency, Mysore, British Burma, Assam, and the North-Western Provinces and Oudh. In Bengal the fall was heavy in many districts. There have also been showers in parts of Bombay, Punjab, Central India and Rajputana.

Harvesting has been completed in parts of the Madras Presidency. Standing crops are generally in good or fair condition, except in Malabar where they have been much injured by want of rain. Locusts still exist in parts of Kurnool, where they are injuring the fruit gardens. In Mysore agricultural prospects continue favourable, but rain is greatly needed in Coorg for the rabi crop, for ploughing, and also for coffee. In the Bombay Presidency kharif sowings continue in several districts though rain is wanted to facilitate operations. Preparations for kharif in Berar, and for rabi in the Nizam's territories are in progress. Ploughing for kharif has commenced in Central India and in Rajputana, where agricultural prospects are generally good. In the Punjab kharif ploughings and sowings are in progress. In the North-Western Provinces and Oudh ploughing is commencing in anticipation of the rains, and showers have already benefited the cane crops. Scarcity of fodder and water is felt in some districts, but the condition of cattle remains good. Preparations for kharif are in active progress in the Central Provinces. In Bengal sowing of aus and amun crops still continues, and paddy, til, and mung—the last in Bhagalpur—are being reaped, with good outturn. Jute, sugar-cane, early paddy, and cheena (millet) are doing well. Sowings continue in Assam, and ploughing has commenced in British Burma.

Smallpox and cholera are generally prevalent, but are abating in the North-Western Provinces, Punjab and British Burma.

Prices are rising in parts of Bengal, the North-Western Provinces and Oudh, and Punjab; elsewhere they are generally stationary.

MADRAS.—General prospects fair.

MYSORE AND COORG.—Rain has also fallen in parts of the province in Simoga district; more rain is required. Agricultural operations in progress; prospects favourable Public health good.

ASSAM.—Weather warm, with occasional rain; more rain wanted. Smallpox still reported from Shastra Barpetta. Prospects of aus good; sugar-cane doing well. Public health fair.—*Pioneer.*

PICKLED PEACHES.—The *Revue Horticole* recommends the young Peaches removed at thinning time to be put into vinegar and pickled like Gherkins. Our contemporary is usually sober in his praises, but he emphasises the pickle as excellent.—*Gardeners' Chronicle.*

GRAPE SEED OIL.—Grape seed oil is (according to the *Corps Gras Industriels*) used in Italy for purposes of illumination. The extraction is principally effected at Modena. It has also long been used for similar purposes in Germany and the Levant. Thirty-three pounds of seed yield about 13 quarts of oil (or about 18 per cent). The seeds of white grapes yield less oil than those of the dark variety, and young vines are said to be more fruitful in this respect than older ones. As to the French varieties, the Rossillar, Aube and Herault seeds yield 2 per cent more than Bordeaux seeds. The colour is a golden yellow, and the oil loses about 25 per cent in purification. —*Journal of the Society of Arts.*

THE BLUE GUM TREE IN IRELAND.—A question having arisen as to the hardiness of Eucalyptus globulus in Ireland, enquiries have been made on the subject, and we learn that on Lord Maurice Fitzgerald's estate at Johnstown Castle, Co. Wexford, the recent hard winters have killed them off, although they had attained 60 feet in height, and had been planted thirteen years. Lord Maurice Fitzgerald has a good many young plants from last year's seed, but is doubtful if they will survive any hard winters that may be experienced in the future.—*Gardeners' Chronicle.*

NATIVE PHOSPHATE OF LIME.—In a recent paper before the American Institute of Mining Engineers, Dr. Sterry Hunt called attention to the extent and importance of the apatite deposits of Canada, existing in parts of the provinces of Ontario and Quebec. These areas have as yet been but partially explored, and much, it is believed, remains to be discovered within them and outlying districts. In 1883 17,840¾ tons of apatite were shipped from Montreal—1,576 to Hamburg, 650 to Stockholm, and the rest to Liverpool, London, and other British ports. This year the shipments are estimated at 24,000 tons, and it is considered that regular mining operations, conducted with skill and a judicious expenditure of capital, would soon make the mining of apatite in these districts of Canada an important industry.—*Overland Mail.*

TROPICAL PRODUCTS AT CALCUTTA.—We are despatching to the Secretary of the Planters' Association a small specimen of the work performed by the morticising machine shown at the Exhibition, which is specially recommended for tea boxes as being cheaper than hand work. Its work is much neater. We also send a sample of Thibetan brick tea and a small one of tea made in the Andaman Islands by the Indian Government prisoners. The Thibetan brick tea appears to be a lot of course leaves wetted and pressed together into a hard dry cake with a smell resembling rank hay rather than tea. The Andaman Island sample is altogether different, being a fair sample of bulk, though very broken. We also forward a tin of Conroy's Malt Coffee, which has a most attractive label attached to it, setting forth its nutritive qualities, and a guarantee that it contains nothing but fine coffee and malt. The firm is a Liverpool one, and we believe exhibited at Calcutta, though we do not know whether they took a prize for these adulterated concoctions. Nothing is said of the precentage the malt bears to the coffee! All these we have but just received from the C. P. A. Commissioner, Mr. Capper, who will doubtless, on his arrival, give the Planters' Association the benefits of what information he has been able to gather in connection with these rival productions.—Local "Times."

THE EUCALYPTUS IN CORNWALL.—The enclosed letter relative to the cultivation of several varieties of Eucalyptus, may interest some of the readers of your paper. I distributed the seed of nineteen varieties to about 500 persons some four or five years ago, for the purpose of ascertaining whether other kinds than the E. globulus was fitted to our climate. The subject is interesting as bearing on the question of the reforesting of Ireland. Several correspondents have assured me that the Eucalyptus globulus grows well and survives the winters in that part of the kingdom.—C. ROBERTS, F.R.C.S., 2, Bolton Row, Mayfair, W.

[See letter in our last issue, p. 678.—ED. *G. C.*]

"Dear Sir,—Some time ago (four years, I think) you were kind enough to send me some Eucalyptus seed. I think I was not successful in raising all the varieties, but found the citriodora, cinerea and sideroxylon grew readily. The former is, I think, acknowledged to be a delicate kind, and I have only allowed plants to remain out in the summer. There is little likelihood that they would stand a cold winter. The cinerea I am inclined to think from my observation is hardier than the more common globulus, and I am pleased to say I have a little tree from your seed which has been out two winters, and is now in bloom. I have hopes that with all the summer before it some of the seed may ripen. The sideroxylon appears also to be tolerably hardy. It has not grown very fast. One plant was out last winter quite unhurt, but it must be said we had very little frost. I have also the amygdalina and globulus—the former out-of-doors two years and the latter three. In a garden near Falmouth, 7 miles from here, and nearer the sea, the globulus has attained a large size, and there are young trees grown from seed ripened there. GEO. HART TAYLOR."—*Gardeners' Chronicle.*

PARAFFIN FOR FRUIT TREES.—Mr. Dunster, in last week's *Field*, says or implies that in his paper in the *Nineteenth Century*, he recommended the paraffin to be used with care "when the sap was down," and that he did not recommend its application to all parts, nor to young wood, &c. I have his article before me now, and it does not contain a word of caution; but, on the contrary, the paraffin is recommended to be "used pure and undiluted," and instead of being described as "dangerous," its application is said "to leave the tree not only uninjured, but with increased vitality and power of productiveness." As to the portion of the wood to be painted with it, he says he painted the trunk and larger branches in his first experiment; but further on, after recording further trials, his advice is that "outer bark of the tree is to be rapidly but thoroughly painted over with it," nothing being said about leaving the young wood. "About the end of summer" or autumn is the time it is to be applied, and as fruit trees are at that season in active growth, with the leaves fresh and green upon them, I leave your readers to judge whether the sap is then "down" or not. The word "miscellaneous" was a misprint. Mr. Dunster's ideas regarding the uselessness of diluting paraffin with water have been proved to be wrong by abundant experience. —S. W.—*Field*.

THE FORESTS OF EUROPE are estimated to cover 500 millions of acres, or nearly 20 per cent of the surface of the Continent. In British North America there are said to be 900 millions of acres of forest, in the United States 560 millions, in South America 700 millions. The total thus estimated for Europe and America alone is equal to 3,600,000 geographical miles, each containing 736 English acres. It is interesting to compare this area, so far as the possible supply of fuel is concerned, with that of the coal-fields of the world, which is estimated at 134,000 geographical miles. Of this area one-twenty-fifth part is in the United Kingdom, or 5,360 geographical miles of forest, against 5,000 geographical miles of coal-fields in full work. Four-fifths of the known coal-measures lie within British and American territory, the forests of Europe and America covering twenty-seven times the area of the known coal-measures of the world. In Baden, where the forest statistics are carefully prepared, the annual production of wood is less than the weight of hay that can be grown on an equal area. At that rate—which is low for an average—each geographical mile of forest will yield, one with another, 1,500 loads of timber per annum. But a square mile of coal-measure yields something like 20,000 tons in the year. The latter produce, however, is limited and exhaustible. Extract the coal, and not only is there an end of the fuel, but the soil itself is generally reduced to utter waste. Arrange the forest according to the best theories of forestry, and its yield is perpetual.—*Builder*.

VEGETATION ON THE CONGO.—Clumps of a dwarf Palm, Phœnix spinosa, which bears a just eatable starveling Date, hedge in these beautiful Orchids from the wash of the river, and seem a sort of water-mark that the tides rarely pass, but the water often leaks through the mud and vegetable barrier, and forms inside the ring of dwarf Palms many little quiet lagoons, not necessarily unhealthy, for the water is changed and stirred by each recurring tide; and in the lagoons bordered by Orchids and tall bushes, with large spatulate leaves and shining white bracts about their flower-stalks [Mussænda], by Pandanus, by waving Oil-Palms, and by Mangrove trees, poised on their many feet, and telling out against the shining sky with their lace-like tracery of leaves—in these quiet stretches of still water are the homes and feeding grounds of myriad forms of life; of blue land-crabs, whose burrows riddle the black soil; of always alert and agitated "mud-fish," flapping and flopping through the ooze; of tiny amethystine red-beaked kingfishers, of kingfishers that are black and white, or large and grey and speckled; of white egrets, of the brown and storklike Scopus umbretta; of spur-winged geese, and of all-devouring vultures. A rustling in the vegetation, and a large voracious lizard slips into the water, or on some trampled bank a crocodile lies asleep in the warm sun with a fixed smirk hanging about his grim muzzle. These lagoons are places seething with life—life that is ever stirring, striving, and active—and when you suddenly arrive, slipping and splashing in the watery footholds, the sudden silence that greets you is rather the frightened hush of a thousand apprehensive creatures.—"The River Congo." by H. H. JOHNSTONE, F.Z.S.—*Gardeners' Chronicle*.

GLUE, PASTE, OR MUCILAGE.—Lehner publishes the following formula for making a liquid paste or glue from starch and acid. Place 5 lb. of potato starch in 6 lb. (3 quarts) of water, and add ¼ lb. of pure nitric acid. Keep it in a warm place, stirring frequently for forty-eight hours. Then boil the mixture until it forms a thick and translucent substance. Dilute with water, if necessary, and filter through a thick cloth. At the same time another paste is made from sugar and gum arabic. Dissolve 5 lb. gum arabic and 1 lb. sugar in 5 lb. of water, and add 1 oz. of nitric acid and heat to boiling. Then mix the above with the starch paste. The resultant paste is liquid, does not mould, and dries on paper with a gloss. It is useful for labels, wrappers, and fine bookbinder's use. Dry pocket glue is made from twelve parts of glue and five parts of sugar. The glue is boiled until entirely dissolved, the sugar dissolved in the hot glue, and the mass evaporated until it hardens on cooling. The hard substance dissolves rapidly in lukewarm water, and is an excellent glue for use on paper.—*P. Notiz*.

PAPER TOWELS.—In the surgical dispensary of the Philadelphia Polyclinic, Dr. Roberts has, we read in the *Medical and Surgical Reporter* of that city, been using with much satisfaction Japanese paper handkerchiefs for drying wounds. Sponges are so seldom and with such difficulty perfectly cleansed after being once used, that they are never employed in the hospital. Ordinary cotton or linen towels are much perferable to sponges, which, if dirty, are liable to interduce septic material into wounds. The paper towels, however, answer the same purpose as cotton ones, and are so cheap that they can be thrown away after being used. The cost of washing a large number of ordinary towels is thus avoided. The paper towels are scarcely suitable for drying hands, after washing, unless several towels be used at once, because a large amount of moisture on the hands soon saturates a single towel. For removing blood from wounds, a paper towel is crumpled up into a sort of ball, and then used as a sponge. Such balls absorb blood rapidly. The crude ornamental pictures, in colour, on the towels, are of no advantage, nor are they, as far as known, any objection.—*Adelaide Observer*.

UNDERGROUND IRRIGATION is thus noticed in the proceedings of the Indian Agri-Horticultural Society:—Read the following letter from Major-General Fischer, R.E., dated Ramandroog, 21st April 1884:—In continuation of my last letter to you, I beg to send you an extract from the *Indian Review* for November 1883, from which it appears that underground irrigation is practised in California. "Four systems of irrigation are practised: first, flooding the land, the second system is by furrows, the third system is by basins dug among tree roots. The fourth system is by sub-irrigation. This is the most expensive system of all, but is thought to economize water. The water is carried in pipes laid from 2 to 3 feet under ground. By opening valves in these pipes the water is let out and up, but never comes about the surface." You will see that I was quite right in not pretending to any original idea, but this does not necessitate the proposal being shelved as it is apparently very suitable to India where it is of the greatest importance to economize water as much as possible, and particularly to prevent loss of water by evaporation which the system adapted in California seems to realize.

DESERT PLANTS.—Several enterprising cultivators are now, at our suggestion, trying to multiply the thornless Opuntia and the Spek-boom in Namaqualand, Angra Pequina, and elsewhere. I think these excellent food plants have not received the attention they deserve. Of course they are special food plants, suited to special localities, and do not come into competition with the ordinary veldt-bosjes and grass wherever the climatic conditions permit the usual pasturage. But I am sure that, should the Spek-boom be incapable of acclimatisation on the sun-smitten roadts of Namaqualand, the Opuntia may be grown in vast thickets at the junction of rock and sand veldt, and its use would save much of the present expenditure in importing compressed hay for trek-cattle. Such culture throughout all carroid districts of the colony subject to frequent failure of seasonal rains is far more important than the introduction of any more of the fancy staples which are from time to time proposed, praised, and forgotten, and which have given point to the proverbial sneer that "the Cape is a country of samples."—M'OWAN, in "Report of the Cape Town Botanic Gardens."—*Gardeners' Chronicle*.

MARKET RATES FOR OLD AND NEW PRODUCTS.

(From Lewis & Peat's London Price Current, June 5th, 1884.)

IMPORTED FROM MALABAR COAST, COCHIN, CEYLON, MADRAS, &c.	QUALITY.	QUOTATIONS.
BEES' WAX, White	Slightly softish to good hard bright	£7 a £8 10s
Yellow	Do. drossy & dark ditto	£5 10s a £6
CINCHONA BARK—		
Crown	Medium to fine Quill	1s 8d a 3s 6d
	Spoke shavings	9d a 3s 6d
	Branch	3d a 8d
,, Red	Medium to good Quill	6d a 3s
	Spoke shavings	5d a 2s 8d
	Branch	3d a 6d
,, Twig		2d a 8d
CARDAMOMS, Malabar	Clipped, bold, bright, fine	5s 6d a 6s
	Middling, stalky & lean	2s 6d a 4s
Aleppee	Fair to fine plump clipped	3s 6d a 4s 6d
Tellicherry	Good to fine	5s 6d a 6s
	Brownish	3s 6d a 5s
Mangalore	Good & fine, washed, bgt.	6s a 7s 3d

CINCHONA CULTURE IN JAVA.

Mr. Van Romunde, who is acting for Mr. Moens as Director of the Cinchona Enterprize in Java, is fortunate in being able to report fairly genial seasons, a great diminution in the insect pest, so destructive in Mr. Moens' time to cinchonas as well as tea plants, and abundance of labour and means of carriage. By this time the railway to Bandoeng will be available so that enterprize, Government and private, ought to receive a new impetus. The "horses" alluded to by Mr. Van Romunde are the ponies for which Java is so celebrated, and as murrain had since 1880 destroyed so many of the cattle on which the Javanese are dependent for the culture of their rice fields, it is of importance that buffaloes should be released from *tavalam* work to take their part in the preparation of the *sawahs* for grain crops. As railways advance in Java and set free horse as well as cattle power, it seems possible that Java ponies, small but fast and with wonderful endurance, may yet be profitably imported into Ceylon. It is amusing to read the details of the "ring" formed by the Java planters to obtain Ledgeriana seed at a low figure, and the measures taken by the Government to circumvent them. In view of the statements as to the scarcity of really valuable seed of first quality, Mr. W. Smith's Ledgeriana seed ought to sell well in Colombo. It will be seen that the "scraping" system of taking bark, which Mr. Moens invented, is still adhered to in Java, and that the experiment of leaving the "wounded" trees without covering was being tried; as also a system of topping the trees and lopping away the lower branches, so as to render the harvesting process easier than it could be in the case of tall trees. It will be seen, that, in combating *Helopeltis Antonii*, Mr. Van Romunde believes great benefit arose, not merely from the capture of the insects, but from the removal and destruction of the infected leaves. These Java reports are always full of interest an interest which they will retain as the cultivation of the finer kinds of *Ledgeriana* progresses in Ceylon. The annual reports for 1880 and 1881 will be found in the number of the *Tropical Agriculturist* for May, and that for 1882 is in course of translation. The main results of Mr. Moens' experience are embodied in his book, which, we are glad to see, is shortly to appear in an English dress

(Translated for the "Ceylon Observer.")

REPORT ON THE GOVERNMENT CINCHONA ENTERPRIZE IN JAVA FOR THE 4TH QUARTER OF 1883.

The weather at the commencement of the past quarter continued very variable. Only in the course of November was it possible to make a beginning with the supplying of the young gardens and the planting of new ones. Harvesting was carried on uninterruptedly on most of the establishments, though less vigorously than during the dry east monsoon. 104,121 Amst. lb. of bark were dispatched to Tjikao in the past quarter. The total quantity of produce gathered and dispatched during 1883 was thus brought up to 410,804 Amst. lb., whilst about 7,000 lb. more are lying in the packing-houses and on the estates ready for dispatch. The supply of means of transport was so great, that the expenses of the dispatch of produce to Tjikao could without doubt again be reduced appreciably. For draught power, horses were alone used, as these appear in the long run to be better suited than buffaloes for transport, whilst the latter can now be used entirely in the cultivation of the sawahs. The scraping method of harvesting was for the third time carried out on the old original Ledgerianas. The trees were this time also shaved over the half of their circumference; the bared parts were not covered, but on this occasion also no signs of suffering in the trees, consequent on the operation, were observed. The good results of the thorough working of the soil during the east monsoon were plainly visible at the setting-in of the rains. Everywhere vigorous growth is to be observed in the plantations. The supply of labour was more than sufficient, in spite of the occurrence of the working of the sawahs and the extension which private cinchona culture has lately undergone. At Nagrak a second erection for the artificial drying of bark is now ready, so that now the harvesting there can be carried on without intermission. The damage caused to the trees by *Helopeltis Antonii* was reduced to a minimum. Strict orders were given to pursue the so much dreaded insect with vigor and as much as possible to extirpate it. Only at Rioenggoenoeng was some damage done to young Ledgeriana gardens, whilst elsewhere only a few sporadic traces of sickness were noticed. On 4th October the second sale of cinchona seed from the Government Gardens was held. In consequence of the small return from this sale, which originated in combinations of private planters, by Government order of 17th Nov. 1883, No. 37, minimum prices have been fixed. For Ledgeriana seed of original trees the price is fixed at *f*2·50 per gram; for seed of typical Ledger descendants at *f*1; for succirubra and officinalis respectively at *f*0·20 and *f*0·05 per gram. On 20th Dec. a large lot of cinchona seed was again sold by public auction at the minimum prices. The result of the sale of October was *f*3,499·75 and of that of December *f*3,760. At the request of a number of private cinchona planters a second sale of Ledgeriana grafts was held on 3rd Nov. Of the 650 slips offered for sale, 300 found buyers at the minimum price of *f*10 each fixed by the Government. So far as is known, the seed and grafts were bought exclusively by Java cinchona planters. In consequence of the lengthy drought in 1883, the old Ledgerianas and the graft plants promise to yield in the course of 1884 an abundant harvest of valuable seed.

VON ROMUNDE,
Director of the Government Cinchona Enterprize.
Bandoeng, 3rd Jan. 1884.

REPORT ON THE GOVERNMENT CINCHONA ENTERPRIZE IN JAVA FOR THE 1ST QUARTER OF 1884

The weather was distinguished by copious rains, which, although they retarded the harvesting a little on some establishments, exercised on the whole a favorable influence on the growth of the plants. By the end of January the whole of the crop of 1883 was dispatched to Tjikao. The harvest totaled 416,740 Amst. lb., of which 2,450 lb. were reserved for the use of the local military medical service. During February 23,946 Amst. lb. of bark, of the crop of 1884, were dispatched to Tjikao, while about 30,000 lb. more are lying ready in the packing-houses and on the estates. This produce will lie stored in the packing-houses until May next, when it can be sent by rail to Batavia. The supply of labor was very plentiful, so that the upkeep of the existing plantations was taken up vigorously, and besides all works necessary or desirable in the interest of the culture were executed. The possibility that during the expected large coffee crop labor might at times fail rendered it desirable that all should be done which under ordinary circumstances would very well admit of delay. The system of scraping of the bark was for the first time practised upon 6 to 7 year

old Ledger seedling plants at Nagrak. The trees were on this occasion also shaved on only half of their circumference, while covering of the wounded parts was entirely neglected. If some trees showed signs of a temporary drooping, that must be referred to the less favorable season at which the operation took place. In future this method of harvesting will be carried out only at the end of the dry season—the period of comparative rest. At Nagrak experiments were made with the topping of the officinalis and Ledgeriana trees chosen for practising the scraping system upon. These experiments were undertaken, as experience had proved that the scraping of trees, especially on sloping ground, to a greater height than 12 feet above the ground, was attended with great difficulties. The attempt is now to form a straight upright stem to about 12 feet and above that a thick crown mass. To get that, an officinalis tree was cut off at 12 feet above the ground. It appeared, however, that many plants which had already got a stem of considerable height lost too many leaves by the operation to continue growing vigorously immediately. In carrying out the experiments on fields of Ledgerianas the high-stemmed trees were topped at 15 to 18 feet, while the younger plants, which had scarcely yet a stem of 6 to 9 feet, were cut off at 12 feet. The intention is, to keep the former at a height of 15 to 18 feet by repeated lopping, and to bring the latter to that height by regular pruning of the lowest branches. The experiment appears, so far as a judgment can be as yet pronounced, to promise good results. It is not improbable that the trees, after having been shaved in two successive years, in the third year, when they will be allowed to rest, that they may renew their bark fully, will yet give a valuable yield in branch and twig bark. Of the ravages caused by *Helopeltis Antonii* is not a trace now to be found However, in the Southern Mountains, where the insect in former years committed such ravages, several women and children continue to be set apart for searching after the insect. Since the trouble has been taken everywhere to collect the leaves affected by the insects, the disease has come to a stand as it were suddenly. The gathering of the affected leaves had for its object the removal of the eggs found in the petioles. The sales of cinchona seed from the Government gardens held on 4th February and 5th March at Bandoeng brought respectively *f*2,010 and *f* 1,520. At the auction the minimum prices fixed by the Government were in no case exceeded. In the report for the 4th quarter of 1883 the expectation was expressed that the original Ledgerianas and the graft plants would in the course of 1884 yield an abundant supply of seed. The result has disappointed expectations: the old Ledgerianas and the graft plants will yield during 1884 only a limited quantity of seed. It is accepted as a rule that for the Government enterprize only Ledgerianas from seed of trees whose bark on analysis yields more than 9 per cent of quinine should be planted.

The comparatively small yield of seed from such trees makes it impossible to offer a portion of it for public sale. There are certainly however to be found among the unexamined trees, of the greater number of which seed is procurable, many with a very high yield of quinine. The plantation at Tirtasari has developed so vigorously during the last few months, that apparently in the course of the second quarter a commencement will have to be made with the thinning out of the now four year old grafts planted on stocks at an average distance of 6 feet.

VAN ROMUNDE,

Directory of the Government Cinchona Enterprize,

Bandoeng, 5th April 1884.

THE GOVERNMENT CINCHONA PLANTATIONS IN BRITISH SIKKIM.

Having dealt with the cinchona enterprize in Java, we publish the main portions of the reports for the year ended March 31st, 1884, on the similar Government enterprize in Northern India. What will strike readers familiar with previous reports is the great revolution which has commenced and is destined to go on in British Sikkim. *Cinchona officinalis* has never, in that region, been a success, and it is now finally condemned. The red barks, too, have begun to give way to the yellow barks; and it seems quite on the cards, that, within half-a-dozen to ten years, the only kinds cultivated in the Darjiling Gardens (and in other places also) will be the best forms of Ledgeriana and those robust hybrids which yield in two instances from nearly 4 to over 6 per cent of sulphate of quinine. Where the Ledgerianas will not flourish, the robust hybrids, originally received in Sikkim from Ceylon, may do well, and the true wisdom will be to cultivate only the best and richest kinds. Carthagena bark is not one of these, and as for the cuprea bark, which is not a true cinchona at all, it is not likely that such an impostor will ever repay cultivation. Mr. Gammie continues to manufacture the febrifuge which has been so useful to the people and so profitable to the Government, and latterly he has turned out a superior crystallized substance, destitute of the amorphous alkaloid to which symptoms of nausea experienced by some patients to whom the febrifuge was administered. It appears, however, that the locally-manufactured substances are likely speedily to be superseded by cheap alkaloids obtained at home from a consignment of bark sent for the purpose. Altogether those Sikkim Cinchona Gardens, originated by Dr. Anderson, have, under the superintendence of Dr. King and the management of Mr. Gammie, been a great success, and have been the means of diffusing very valuable information, by which private planters have largely benefitted.

On cinchona planting generally and the value of quinine in the market and as a medicine, the following flippant deliverance appears in an Indian journal:—

Cinchona planting in Southern India looks as if it was being overdone. Every disconsolate coffee or tea planter who has a few acres of land to spare hastens to plant them with cinchona, forgetful, it would seem, of the enormous acreage in India, Ceylon and elsewhere, that is under cinchona already. Moreover the faculty, once its best friends, are beginning to turn their backs on Peruvian bark. Quinine is on the high road to being played out. So long as the drug was a guinea an ounce it was of course prescribed freely, but now that it can be bought for a few shillings, and soon perhaps will be purchaseable for a few pence, it is not astonishing to hear that it is of no greater efficacy than simple "bitters." Certainly cinchona promised well a few years ago, but it is not to be expected that when every one—man, woman and child—plants cinchona, cinchona will pay. It is the desperate resource rather of persons who have been nauseated by their experiences of tea and coffee. A new product is a desideratum in the eyes of all planters of the South, and why not "bitters?" Tea and coffee land will always grow oranges, citrons, and limes in profusion, and, strange to say, these are things that are not played out, and probably never will be so long as the world's thirst for "cocktails" continues. It is hard to resign the exaggerated hopes that cinchona once held out, but the prudent planter will have as many strings to his bow

as be can. And no doubt there is money to be made out of orange bitters, lime juice, and such like things, although less attractive in themselves than the gold and the cinchona of a highly imaginative past.—*Pioneer.*

Quinine and the allied alkaloids have certainly fallen in price, but not in medicinal value; and however cinchona planters may have suffered, humanity at large will benefit enormously by the cheapening of febrifuges. Like tea, coffee and sugar, the cinchona alkaloids are destined to go on increasing in consumption until they are available to every fever-stricken patient. As to lemon-juice, one additional plantation of limes would flood the market, while the less people indulge in bitters the better.

ANNUAL REPORT ON THE GOVERNMENT CINCHONA PLANTATION IN BENGAL FOR THE YEAR 1883-84.

No. 34c, dated Royal Botanic Garden, Seebpore, near Calcutta, the 19th April 1884.

From—Surgeon-Major G. King, M. B., Superintendent, Royal Botanic Gardeu, Calcutta, and in charge of Cinchona cultivation in Bengal. To—The Secretary to the Government of Bengal, Financial Department.

I have the honour herewith to submit the annual report on the Government Cinchona plantations in Bengal for the year ending 31st March 1884.

Twenty-second Annual Report of the Government Cinchona plantation in British Sikkim by Surgeon-Major G. King, M. B., F. L. S., Superintendent of the Royal Botanic Garden, Calcutta, and of Cinchona Cultivation in Bengal.

The total number of trees on the plantations at the end of the year was 4,740,811 of all sorts. This is an increase of 29,643 on the former year. But although the net result has thus been but little affected, a considerable change in the proportions of the different species in cultivation has resulted from the operations of the year. The general effect of those changes is a decrease in the number of red bark and an increase in number of the yellow bark trees. In the Mungpoo and Sittong plantations, 232,200 red barks were uprooted, and only 51,000 were planted. On the other hand 172,520 trees of *Calisaya* were planted out on those older plantations as against 15,000 which either died or were thinned out in spots where there was a tendency to overcrowding; while on the new plantation at Rungjung 42,200 trees were planted out. The total of yellow barks planted was therefore 214,720 and these were all either of *Ledgerianas* from plantation seed, or *Verdes* and *Moradas* from South American seed supplied during the former year by the Secretary of State. I have in former reports alluded to the forms of cinchona intermediate between *Officinalis* and *Su cirubra*, which many years ago first appeared on the plantation and which have been referred to as *hybrids*. And I have from time to time published, under numbers, analyses of the barks of these various forms. In my last report, analyses of the bark of eight of these were published, and I then pointed out that No. 4 is a poor bark, not much superior to *Succirubra* as a yielder of quinine. Plants of this sort, to the number of 33,878 was therefore uprooted during the year; and instead of them there were planted 50,000 of the forms yielding richer bark. At Rungbee 5,000 trees of *Officinalis*, which had become sickly, were cut out and as this species does not thrive well in Sikkim, none of it were planted. The total number of trees of all sorts at the plantations on the 31st March is shown in the following table, while the exact details of each plantation will be found as appendices to this report.

Division.	Red cinchona. Succirubra.	Yellow cin. Cal. ledgeriana.	Yellow cin. Cal. verde and morada.	Hybrid unnamed variety.	Other kinds.	Total of all sorts.
Mungpoo	2,132,000	754,218	7,300	280,500	25,593	3,499,611
Sittong	1,100,000	59,000	...	40,000	...	1,199,000
Rungjung	...	41,000	1,200	...	...	42,200
Grand Total of all kinds.	3,532,000	854,218	8,500	320,500	25,593	4,740,811

During the year Mr. Gammie observed in the plantation two forms of hybrid, the bark of which had not hitherto been analysed. An analysis has now been made of each bark, and the results are here given;—

Analysis of samples of hybrid bark from Mungpoo.

	No. 9.	No. 10.
Crystallized sulphate of quinine ...	3·12	3·24
Ditto ditto of cinchonidine ...	1·21	2·46
Ditto ditto of quinidine ...	0·30	...
Cinchonine (alkaloid)	0·71	0·52

For convenience of reference, I submit as an appendix a table giving the analyses of the barks of all the ten forms of hybrid which we now recognize. Many of these, it will be observed, are excellent barks, and the trees producing them being for the most part strong rapid growers, they are well worthy of cultivation. Mention has above been made of two kinds of Cinchona called *Verde* and *Morada*, which, at least under these names, are new to the plantation. These were raised from seeds from South America, which were, at my suggestion, indented for from the India Office about eighteen months ago. The seed germinated freely, but many of the seedlings came up of a peculiar golden yellow colour, and these all died off when they were hardly half an inch in height. The cold season was an unusually severe one, and Mr. Gammie reports that, in spite of all precautions, a considerable number of the weaker survivors succumbed to the low temperature. The remaining plants are healthy, and as many of them resemble in appearance varieties which we know by analyses to be good quinine-yielders, the result of the importation of South American seed promises to be satisfactory. The new plantation at Rungjung, which was opened about eighteen months ago, promises very well, the Cinchonas permanently planted out in it being robust and healthy. As explained in my last report, this plantation is at a considerable distance from Mungpoo, and is under the immediate charge of an Assistant (Mr. Parkes), but is frequently visited by Mr. Gammie. I inspected it during the year and was well pleased with its appearance. The older plantations at Rungbee, Mungpoo, and Sittong continue to thrive very well.

2. *Details of the year's crop.*—The crop of the year amounted to 305,160 pounds of dry bark in the following proportions:—283,240 pounds red, 14,320 pounds *Calisaya*, 5,490 *hybrid*, and 2,110 pounds *Officinalis*. This brings the total yield of the plantation from its beginning up to 2,917,726 pounds of dry bark. The year's crop as usual was obtained partly from trees thinned out where overcrowding was beginning to occur or from more or less mature trees uprooted for the sake of their bark. About a sixth part of the crop (51,890 pounds) was obtained from the young plantation at Sittong, which may now therefore be considered as having come into bearing. Only a small quantity of bark (31½ pounds) was sold during the year, and 100 pounds were supplied to the Calcutta Medical Depot. Practically the whole crop was therefore made over to the Factory, and it will be found accounted for in the Factory Report. I regret to say that no accounts have as yet been received from the India Office of 41,800 pounds of bark sent to London during the previous year. I am still therefore unable to include the proceeds of this consignment in the plantation accounts.

3. *Expenditure for the year.*—The total budget grant for the year was R93,605, but of this only R78,660-4-8 were spent, thus leaving a saving of R14,944-11-4. Of the amount expended, the young plantation at Rungjung absorbed R12,527-1-9 and the balance was spent on what has hitherto been termed the old plantations, namely Rungbee and Mungpoo and on the intermediate plantation of Sittong. Up to the beginning of the year under review the expenditure on Sittong has been treated as capital, and has been charged to Block account, and the expenditure on Rungbee and Mungpoo has been treated as working expenses against which there has been put the annual bark crop. But the Sittong plantation has now come into bearing, and I have this year united Sittong to the old plantation, increasing the capital of the united plantation by the total sum expended on Sittong, and including the year's expenditure on Sittong as part of the working expenses of the united plantation. The figures therefore arrange themselves thus:—

				R.	A.	P.
Total expenditure for year 1883-84			...	78,660	4	8
Capital Expenditure.						
		R.	A.	P.		
On Rungjung (new plantation)		10,527	1	9		
Proportion of European establishment	...	2,000	0	0		
Working Expenses.						
On upkeep of plantations of Rungbee, Mungpoo, and Sittong, and in the production of 305,160 pounds of bark...		66,133	2	11		
					78,660	4 8

If the total cost of the crop be divided by the number of pounds of bark of which it consisted, the price of the latter per pound is thus seen to be annas 3 pies 5·61. This is higher than the rate per pound for the crop of the previous year, which was only annas 2 pies 9·88 per pound and the difference is due to the smaller crop harvested, viz. 305,160 pounds as against 358,100 pounds for 1882-83. These fluctuations are inevitable as long as the crop continues to be limited, not by the capacity of the plantation to produce, but by the demand for the product into which the crop is to be manufactured. The lowest price of production per pound can of course only be reached when the plantation is cropped to its full capacity to yield. The capital of the old plantations of Rungbee, and Mungpoo stands at ten lakhs of rupees To this has now to be added the expenditure on Sittong from its commencement in 1875-76 to the 31st March 1883. This, with compound interest at 4 per cent. but with a deduction on account of the bark yielded by the plantation during the past few years, amounts to R71,722. This sum, added to the ten lakhs for Rungbee and Mungpoo, brings the capital of the united plantation up to R10,71,722.

4. *Carthagena Bark.*—At the end of the previous year, three plants remained of the species yielding the hard Carthagena bark of commerce. These were planted out in what was considered a very favourable spot. I regret, however, to say that two died during the year, and that we are now thus reduced to a single plant. This Carthagena bark has been a cause of disappointment for several years past, which is all the more provoking as, when first received from Kew, the plants promised to do well. It is now pretty clear that the climate of Sikkim is unsuitable for it; but this is less to be regretted as the bark is not a very valuable one, and is not to be compared for a moment to that of *Ledgeriana* or of our hybrids.

5. *Cuprea Bark.*—This bark which, although it yields quinine, is not the produce of any Cinchona, but of the allied genus Remija, continues to be poured into the London market in large quantities. Little is known of the conditions under which Remija grows, but from the low rate at which it can be shipped from South America, it is probable that it is the product of a quickly growing or very hardy plant. I have therefore for some time been anxious to get seed of it for trial on the plantation. As yet I have succeeded in getting only two packets of seed. From the first of these only a single plant resulted, and that speedily died. A second packet more recently received was sown towards the end of the year, but the results are not yet known.

6. *Distribution of plants and seeds.*—As it is the desire of Government to spread the cultivation of the best kinds of Cinchona as widely as possible, all the spare seed of our *Ledgeriana* trees is distributed gratuitously as soon as it ripens. During the past year about 200 packets were sent out to as many planters mostly in Southern India and Ceylon. The seed-bearing trees, both of *Ledgeriana* and the hybrids, have now been well isolated, so that cross fertilization by insects visiting inferior species is prevented, and the high quality of the offspring is, to a certain extent, ensured. During the year, 84,000 seedling trees were sold to planters in the district, and the proceeds were credited to Government.

7. *Land rent and grazing dues.*—The sum collected for rent and grazing from settlers within the reserve amounted to R1,749·5. This was paid into the Darjeeling Treasury and does not appear amongst the plantation receipts.

8. *Estimated crop of* 1884-85.—The crop to be taken for the current year will depend as usual on the requirements of the Factory. As quinine is very cheap at present, and as it appears likely to remain so for some time, the demand for febrifuge will probably fall off to some extent, and the crop for the current year will be correspondingly diminished.

9. The fuel plantation continues to receive attention and to be extended as circumstances admit.

10. During the year Mr. Gammie has been in executive charge of the plantation, and has worked with his usual ability and energy, Mr. Pantling, the Senior Assistant, Mr. Parkes, the Assistant in charge of Rungjung, and Messrs. Crofton, Kennedy and Gammie, junior, have all worked heartily and well.

QUINOLOGIST'S REPORT FOR 1883-84.

No. 5, dated Royal Botanic Garden, Seebpore, near Calcutta, the 19th April 1884.

From—Surgeon-Major G. King, M. B., Superintendent, Royal Botanic Gardens, Calcutta, and of Cinchona Cultivation in Bengal, and Offg. Government Quinologist,

To—The Secretary to the Government of Bengal, Financial Department.

I have the honor herewith to submit the annual report of the Quinologist for the year ending 31st March 1884.

At the Factory, which is still located on the plantation, work went on as usual, Mr. Gammie being in immediate charge. The total outturn for the year was 8,714 pounds of febrifuge, of which 250 pounds were of the new crystalline preparation. This new drug in appearance closely resembles the ordinary febrifuge, but on examination the grains are seen to be small crystals. In constitution it differs, however, materially from the old febrifuge, inasmuch as it contains none of the amorphous alkaloid which is the ingredient in the old febrifuge which causes the nausea that sometimes follows its administration. The percentage of febrifuge obtained from the bark used in the manufacture was almost exactly the same as in the previous year, viz. 2·728 per cent.

The cost price of the febrifuge comes out at R10-4-8 per pound, which is in excess of the cost of the outturn of last year. The increase in price depends mainly on the higher rate per pound of the bark collected during the past year, which, as is explained in the plantation report, is due to the full crop for the year not having been gathered.

The distribution of febrifuge for the year was 9,144¾ pounds, being 117½ pounds in excess of the issue for 1882-83.

Including the issues for the year under review, the total distribution of febrifuge from the Factory since the beginning (eight years ago) now reaches the high figure of 61,321 pounds 5 ounces, and the manufacture during the same period amounts to 64,026 pounds 13 ounces.

From these figures it appears that the financial result for the year is a net profit of R59,700-7-7 which (the capital being R10,71,722) is equal to a dividend of about 5½ per cent. But it must be remembered that the capital has already been returned to Government more than twice over in the shape of the savings effected during the past eight years by the substitution of cinchona febrifuge for quinine. This saving has been added to in the past year, during which 4,850½ pounds of febrifuge have been used in Government institutions at a cost of R80,045, whereas an equal quantity of quinine would, even at the present low price of quinine, have cost at least three times as much.

Mr. Gammie has been in charge of the Factory during the year, and his services as in former years demand my best acknowledgments. The head of my office, Baboo Gopal Chundra Dutta, has conducted his duties to my satisfaction.

As usual I append in a tabular form the details of the cash receipts and credits for sales of bark and febrifuge. In this statement credit is taken for all the febrifuge supplied to the Surgeon-General and Inspector-General of Jails, Bengal, although as a matter of fact the final adjustments of all the quantities supplied on the indents of these officers has not yet been actually made in the Accountant-General's office.

FINANCIAL DEPARTMENT.

AGRICULTURE.

Darjeeling, 30th May 1884.

Resolution.

Read—The annual report of the Government Cinchona Plantation in Bengal for the year 1883-84, and the annual report of the Quinologist for the same year.

A considerable change was effected during the year in the proportions of the different species of cinchona under cultivation. In the plantations at Mungpoo and Sittong, some 232,200 red bark trees were uprooted, and these were replaced chiefly by the yellow bark variety. The new plantation at Rungjung was also planted out with 42,200 trees of this variety. This reform has been introduced at the instance of the Home Government, the Secretary of State being desirous of extending the cultivation of the *Calisaya Ledgerina* species, which is far richer in quinine than the red bark variety. The total number of yellow barks planted was 214,720, and these were either *Ledgerianas* from plantation seed, or *Verdes* and *Moradas* from South America. The latter plants were raised from seed which had been supplied in the preceding year by the Secretary of State. The seed germinated freely enough, but a considerable number of the seedlings died when they were hardly half an inch in height; while the weaker surviving plants succumbed to the effects of the winter, which was unusually severe. The remaining plants look healthy and promise to be good quinine-yielders.

2. In the resolution recorded upon the proceedings of last year, analyses were given of barks of eight forms of the hybrid variety. During the year under review, barks of two more of these were analysed. The results obtained from all the ten hybrids are shown in the following table :—

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.
Crystallized sulphate of quinine...	2·87	1·48	1·88	0·97	2·12
Crystallized sulphate of cinchonidine	2·94	2·85	2·93	1·94	2·84
Crystallized sulphate of quinine...	traces.	traces.	traces.	traces.	traces.
Cinchonine (alkaloid)...	0·72	0·57	0·52	0·80	0·33

	No. 6.	No. 7.	No. 8.	No. 9.	No. 10
Crystallized sulphate of quinine...	2·04	6·12	3·99	3·12	3·24
Crystallized sulphate of cinchonidine	2·26	2·46	3·33	1·21	2·46
Crystallized sulphate of quinine...	traces.	traces.	traces.	0·30	...
Cinchonine (alkaloid)...	0·68	0·55	0·57	0·71	0·52

Most of these are excellent barks, and the trees producing them are, as the Superintendent remarks, well worthy of cultivation.

3. The total number of Cinchona trees of all sorts at the close of the year was 4,740,811, namely red (*Cinchona Succirubra*) 3,532,000, yellow *Calisaya Ledgeriana*) 854,218, yellow (*Calisaya Verde* and *Morada*) 8,500, hybrid unnamed variety 320,500, and other kinds 25,593. The total number planted in the preceding year was 4,711,168.

4. The entire produce of the plantations for the year was 305,160 lb. of dry bark. Of this, 283,240 lb. were of red, 14,320 lb. of *Calisaya*, 5,490 lb. of hybrid, and 2,110 lb. of *Officinalis* bark. The Sittong plantation may now be considered to have come into bearing, a sixth part of the total crop having been obtained from it. With the exception of 100 lb. supplied to the Calcutta Medical Depot and 31½ lb. sold to the public, the entire produce was made over to the febrifuge Factory for disposal.

5. The total expenditure on the plantations amounted to R78,660, against the budget allotment of R93,605. Of this expenditure, R12,527 was incurred on the young plantation at Rungjung, and this sum is chargeable to capital account. The balance, amounting to R66,133, was spent on the old plantations at Rungbee, Mungpoo and Sittong. The expenditure at Sittong, which was formerly charged to block account, has, now that the plantation has commenced to yield a crop, been charged as working expenses in the same manner as the expenditure on the Rungbee and Mungpoo plantations is treated.

6. Judging from the results of the experiments made for several years past to grow on the plantations the plants yielding the *Carthagena* bark, it is established, almost beyond doubt, that the plant is unsuited to the climate of Sikkim. The bark, however, is not so valuable as that of the *Ledgeriana*, or the hybrid variety grown on the plantations. In the last year's resolution, reference was made to the *Remija* plant, which produces a quinine-yielding bark under the name of *Cuprea*, and it was stated that this bark formed a very large proportion of the quantity of quinine bark imported into Europe. Dr. King has hitherto succeeded in getting only two packets of this seed. The plant raised from one of these speedily died, while the seed contained in the second packet was only sown towards the end of the year, and the result is not yet known.

7. The percentage of febrifuge obtained from the bark was almost the same as in the previous year, viz. 2·72 per cent., but the cost at which the febrifuge was turned out rose from R8-8 a pound to R10-4-8 a pound. This increase is attributed to the higher cost per pound of the bark collected during the year, which was due to the smaller crop harvested. Dr. King explains :—"The difference is due to the smaller crop harvested, viz. 305,160 lb. as against 358,100 lb. for 1882-83. These fluctuations are inevitable as long as the crop continues to be limited, not by the capacity of the plantation to produce, but by the demand for the product into which the crop is to be manufactured. The lowest price of production per pound can of course only be reached when the plantation is cropped to its full capacity to yield." The distribution of the febrifuge was in excess of the issues for 1882-83. The figures for the two years are :—

	1882-83. lb.	oz.	1883-84. lb.	oz.
The Medical Depot, Calcutta...	2,000	0	2,620	0
Do Bombay...	1,000	0	1,000	0
Do Madras ...	350	0	580	0
To Colonial Government Mauritius ...	150	0	.....	
„ Surgeon-General (for district medical officers of Bengal) ...	803	12	618	4
„ Inspector-General of Jails (for jails and lock-ups, Bengal) ...	26	12	32	4
Sold to the public... ...	4,560	12	4,276	0
Given as samples	10	0	18	4
Total...	8,901	4	9,144	12

The issues to the public declined during the year though they are still in advance of those of 1880-81. It is probable that a supply of English-made febrifuge will shortly be sent out to this country for sale at a very low rate in malarious tracts. It is hoped that its cheapness will induce the poorer classes to have recourse to it, and they will thereby have a better opportunity of discovering and appreciating its value.

8. The revenue derived from the sale of the febrifuge, seed, plants and bark amounted to R1,54,463-14-0, as shown below, against R1,52,807-1-0 in the preceding year—

	R.	A.	P
By sale of febrifuge, seed, plants, and bark to the public	74,264	10	0
By credits from the Medical Depôt of Calcutta	43,384	4	0
Ditto ditto of Bombay	16,500	0	0
Ditto ditto ... of Madras	9,570	0	0
Ditto from the Surgeon-General, Bengal	10,2118	0	
Ditto from the Inspector-General of Jails, Bengal	533	8	0
Total ...	1,54,463	14	0

The result of the year's working was a net profit of R59,700-7-7, equal to a dividend of 5½ per cent. on the capital outlay. Dr. King points out that this does not represent the whole of the actual gain for the year. The cost of the febrifuge used in substitution for quinine in Government hospitals and dispensaries during the year was R80,045, whereas an equal quantity of quinine would have cost three times as much.

9. The Lieutenant-Governor is again glad to acknowledge Dr. King's excellent management of his department during the year. He fully appreciates the services of Mr. Gammie, who held immediate charge of the factory. The other assistants are also well spoken of.

ORDER.—Ordered that a copy of this Resolution, and of the Reports referred to, be submitted to the Government of India, in the Home Department, and that a copy of the Resolution be forwarded to the Superintendent of the Cinchona plantations, for information.

Ordered further that a copy of this Resolution, and of the Reports, be forwarded to the Medical Department of this Government, and also to the Government of Madras, and to the Surgeon-General, Bengal, for information.

By order of the Lieutenant-Governor of Bengal,
E. N. Baker,
Offg. Secretary to the Government of Bengal.

THE SOAP BARK TREE.

This tropical tree would probably be a valuable one to cultivators if it would take kindly to our Ceylon soil. We believe that Mr. Nock is already growing it at the Hakgala Experimental Botanic Gardens and that a few plants might be obtained from him. The *Adelaide Observer* refers to it as follows :—

The Soap Bark Tree (Quillaja Saponaria Mol.), a native of Chili, belonging to the natural order of Rosaceæ. Through the kindness of Sir Joseph Hooker I received some seed of this remarkable tree. The bark consists of numerous layers, containing much carbonate of lime and other mineral matters, which renders it so heavy that it sinks in water. It is in common use in Chili instead of soap, and has been introduced into England and recommended as a substitute for soap, especially for washing printed goods, silks, and delicate coloured fabrics. Being a tropical tree, I doubt if it will thrive with us out of doors. I therefore sent the seed to the Government garden at Palmerston, where, no doubt, the tree will thrive better.

The following is what is said about it in the *Treasury of Botany* :—

Quillaja Saponaria, the Quillaia or Cullay of the Chilians, is a tree from 50 to 60 feet high, with smooth shining short-stalked oval leaves ; and usually terminal white flowers, either solitary or from three to five on a stalk, Its bark, called Quillaja or soap-bark, is rough and dark coloured externally, but internally consists of numerous regular whitish or yellowish layers, and contains a large quantity of lime and other mineral matters. It is rich in *saponine*, a vegetable soap principle found likewise in plants belonging to the clovewort, soapwort, and a few other orders ; and on this account it is commonly used as a substitute for washing clothes, two ounces of the bark being sufficient to wash a dress. It is also said to remove all spots or stains, and to impart a remarkable lustre to wool : and it is used to wash the hair, for which purpose it is powdered between stones, then rubbed with the hands in water, making a foam like soap. A preparation of it has lately been brought into use in this country for promoting the growth of the hair.

THE INDIARUBBER-YIELDING CREEPER.

Some time ago a Ceylon planter addressed a letter to M. H. Pierre, under the impression that he was still Director of the Botanical Gardens, Saigon, asking for information regarding the caoutchouc-yielding creeper, *Parameria glandulifera*. The reply, in French, was sent to us for insertion, and, having had it translated, we place it below. We saw a gum-yielding creeper at Henaratgoda, but we do not know whether it was the plant now referred to or the African species which Dr. Kirk took so much pains to introduce. Dr. Trimen will see that he is specially referred to by M. Pierre, and we have no doubt he will respond with such information as is available. It seems now pretty clear, that, if the enterprize of growing rubber-yielding trees is to succeed in European hands, a species or variety must be cultivated richer in gum than the Ceará plant has yet proved itself to be. The failure of regular culture would be a great misfortune, for it would mean the extirpation of most of the trees which yield caoutchouc.

Leyden, 25th December 1883.

Sir,—As I was travelling, I was unable ere this to reply to your letter of 29th October 1883, and cannot do so in your language, not being able to handle it sufficiently correctly, to my great regret.

I retired from the direction of the Botanic Gardens at Saigon many years ago, and could not help you in obtaining the seeds which you wish of *Parameria glandulifera*.

However, this plant was many years ago introduced by me into that garden, and, I am glad to think, continues to grow there. It is reproduced *very easily* from cuttings, and its growth is rapid. It is possible that it exists in the Botanic Gardens at Peradeniya (Ceylon), and Mr. Trimen, the learned director of that garden, would be pleased to communicate with you on the subject and send you plants if he possess them.

The *Parameria glandulifera* is very abundant on the Nilgiris, in the south of the Ceylon peninsula [Jaffna], in the peninsula of Malacca, in all Malasia, in the Philippines and in Indo-China.

It is a creeper, the stem of which, when it is mature, is from 9 to 10 centimetres in diameter. Its milky juice is very abundant, and if it is boiled (with the addition of water) at a temperature of 30 to 40 degrees [centigrade] it collects into a mass of caoutchouc of very fine quality. It is enough, during the boiling, to stir the milky mass with a stick, and the caoutchouc adheres to it. I made this experiment in the mountains of Cam Chay in Cambodia in 1874. I also sent to Kew a fragment of caoutchouc which this operation yielded, with a specimen of the plant dried.

This is the sum of my experiments. When I left Saigon in 1877 the plant introduced was already more than 19 metres high, encircling the stem of a *Tectona grandis* (teak). I cannot tell you what its yield per hectare is, not having been able to make the necessary experiments. The plant grows equally well on the plains and on the hills. It is very common at a height of 900 metres and at sea-level. It is probable that the coagulation of the milky sap could also be brought about, as in the case of certain caoutchoucs of Borneo, also belonging to the family of the *Apocyneæ*, by adding either salt or alum to the milky mass, in certain proportions, not difficult to determine. This plant ought to be cultivated in forests at the foot of trees. I mention this method, although any other mode of culture may be equally advantageous, as, in a forest, one would necessarily economize in the matter of supports, which is a consideration.

I regret, sir, not to be able to furnish you with more details and to be in some way useful to you. I should have done so most willingly, as it is a matter of congratulation to see the European race turning its efforts to the culture of tropical lands.—

Accept, &c.,
H. Pierre.

THE MANUFACTURE OF TEA.

A juvenile assistant on a place that I have the management of, sends me this paper and asks for machinery. I think he should have it. Saving in manufacture and care and watchfulness, combined with skill in turning out a superior article of commerce, should be the aim of the capitalist who hopes to secure the highest returns on his outlay. Mere yield of so many lb. of leaf is of itself but a poor satisfaction to the planter if he does not make a good tea, and at little cost. Tea ranks as a manufactured article as much as cocoatina or chocolate or even woollen and linen fabrics. It is not strictly a mere tropical product we are dealing with, like coffee or cinchona,

If it is tea leaf, why it is the grass which flourishes today and is cast into the oven tomorrow. Tea manufacture is therefore as distinct from planting as cotton-growing and sheep-farming are from the linen and woollen trade of the great cities in England. When a garden yields 500 lb. a day, it is time it had machinery.

AGRICOLA.

A Day's Work on a Young Tea Estate.

To manufacture 500 lb. or say 480 lb. of green leaf, as a daily average:—

Plucking at 2c. per lb. or 12½ lb. per head	R9·60
Rolling at 40 lb. per cooly, 12 coolies at 37c. ...	4·44
Firing at 80 lb. per head, 6 coolies at 37c.	2·22
Charcoal 4 cwt. 1 qr...	4·25

Items common to both modes of operation have been omitted to simplify the figures. It professes also to be only a rough calculation. The cost of charcoal will be found to be a formidable item. It is about twice the cost of labour in firing fully the value of the cost of rolling and about half the value of plucking. While rolling, firing and charcoal together represent figures exceeding the cost of plucking, the figures being plucking R9·60, representing the field-work, and manufacture or store-work R10·91—total R20·51 for about from 100 lb. to 110 lb. of good tea, making allowance for coarse leaf, wet leaf, &c.

With machinery:—

Plucking		R9·60
Sirocco firing 1 cooly	37c.	
Sirocco wood cutters 2 at 37c. ..	74c.	
Roller .. .. .. 1 at 37c. ..	37c.	R1·48

If with hand-roller the cost will still be the same, as four men rolling one-and-half hour will be equal only to one man's work of six hours. The cooly works ten hours a day for 37 cents. Total cost of rolling and firing R1·48 per diem or a saving of R9·43, a saving equal to nearly the full cost of plucking. Thus an estate without machinery spends about twice as much (roughly speaking) in producing the same quantity of tea with, if anything, a quality inferior to the machine-rolled and machine-fired tea.

A saving of R9·43, say R10 a day, in a field of 50 acres or thereabouts yielding about 500 lb. of leaf daily will yield a profit to the owners of about from R250 to R300 per month. If the yield doubles, the profits would increase too in mathematical proportion. For R5,000 to R6,000 a year will be about the profit on a tea estate of 100 acres yielding from 6,000 lb. to 8,000 lb. of tea per month. This from machinery alone. Interest of value of machine must be added to this as a separate item.

THE WEATHER AND THE CROPS.

In our issue of the 23rd instant, we mentioned that the same mild weather which we are experiencing in Colombo was also prevailing in the mountain regions. We now learn from a passenger who travelled down from Lindula *via* Hatton, that after a few showers during Monday night, the morning cleared up and the sun blazed with fierce heat from an almost cloudless sky through the whole of Tuesday: so intolerable, indeed, were its rays that up to 5-30 p.m. they had to be carefully excluded from the railway-carriage. Of course up in the hills the clouds gather as dusk comes on and do not dissipate till the day is some hours old, having during the night-hours distilled some of their precious moisture, so that this monsoon is considered by planters to be "a first-rate planting season." We suspect this opinion is founded a good deal upon the fact that most people are putting in the sturdy tea plant which defies almost any extreme of weather and bad treatment, while the delicate cinchona and coffee have scarcely a thought given to them. In Lindula and the Kotigaloya Valley gangs were busy interlining the coffee, while on the Dikoya side jungle and abandoned coffee, were being opened out, and cultivated coffee was being lined and holed, for tea. Near Mariawatte also a new clearing is to be seen—presumably for tea. There is no doubt that within the next five years the producing acreage of tea will have been enormously extended. It would be almost presumption now to doubt the success of this new product in any part of Ceylon with the results in yield and price before us of such estates as Culloden at sea-level, Galboda at 2,500 ft., Loolcondura at 4,500 ft., and Rookwood and Abbotsford at 4,600 to 6,000 ft. above the sea. We hope to be able to publish statistics at the end of 1884 showing that this last estate will have given a yield exceeding 600lb. per acre against 425 lb. last year; at the same time giving an average value of 1s 3d per lb. for the whole produce, dust inclusive, showing that a fair plucking is performed, neither too coarse for quantity, nor too fine for quality. The manager of this estate informs us that a small patch which a fortnight ago was badly affected with red spider and Helopeltis has now completely shaken them off and is flushing vigorously. The growth of all vegetable life at present is marvellous. The unusual drought has told most favorably upon coffee, and everywhere the bushes (except the most *abandoned* ones) are loaded with crop or young branches, the future producers of crop. Everyone will rejoice to hear that Logie is to give the biggest crop it ever had, and we know several cases where the yield will be three or four times that of last year. So that it is an ill-wind that blows nobody any good. If this drought has been prejudicial to tea in some districts, and we have received complaints to that effect, it has been good generally for coffee and cinchona, and in other districts so favourable has it been for the growth of leaf that the flush cannot be overtaken. We believe Imbulpitiya is suffering from this happy plethora. Three weeks ago Mr. Scovell of Strathellie informed us that he had just made 5,000 lb. of prepared tea in one week, having manufactured over 1,000 lb. in one day. In view of such figures as these, the Ceylon and home Governments ought not to hesitate one day longer as to the expediency and urgency of railway extension. For every 100 acres of tea in bearing the railway ought yearly to receive consignments amounting to 35 to 50 tons (including chests and lead) down, besides all the rice, manure, charcoal, shooks, lead, nails, hoop-iron and machinery up. Already the Hatton extension is doing good service. A few days after it was opened it conveyed safely and expeditiously a Sirocco dryer up, and we heard that the goods-shed was crammed; the day after the opening, Galbodda sent down 5 tons of tea, and on Tuesday the Galboda goods-shed was piled up with tea chests bearing the well-known mark K A W. One inconvenience which we hope will soon be remedied is the non-supply of horse and carriage trucks, so that traps have still to be sent *via* Nawalapitiya. Another great inconvenience surely to strangers and to those not fortunate enough (or with too much delicacy) to have friends near Hatton is the utter absence of anything like a resthouse where to obtain refreshment or a night's lodging. But a great convenience which almost makes up for the latter want is the running of the Dikoya and Dimbula-Nuwara Eliya coaches, which, we are glad to learn, are being freely patronized.

THE PREPARATION OF TEA.

Our readers will be interested in the following details the most noteworthy of which is that by means of pans even an expert person in China can fire only 3 or 4 lb. daily.

General Mesny writes to us from Soochow, under date of May 26th, as follows:—

I have just met a Mr. Hu, who is a native of Hui-chou Fu, in An-hui, and whose family has for three generations been employed in the preparation of tea for the English market. That kind of tea, called Mo-yune, so highly prized in

England, comes from friend Hu's native place. He tells me that it owes much of its excellence to careful manipulation when firing. The firing pans are, he tells me, always laid with their edges horizontal, so that they are heated on all sides uniformly, the greatest heat being of course at the bottom, nearest the fire, whence it radiates equally all around. An expert person can fire in a proper manner only three or four pounds of tea daily. A small quantity, about as much as a person can hold in both hands, is placed in the pan at a time, and is constantly worked in a manner to roll the leaves whilst the firing is going on. Mr. Hu informs me that heavy losses have been sustained in the tea trade of late years.

Tea being much cheaper than formerly, it is impossible to make anything out of it. In former years these teas were carried to Canton for sale, and brought fine prices. Of late years, however, there is generally a loss of twerty per cent. on cost of production, my informant says, but how they can manage to carry on a trade under such circumstances I cannot understand.

Hu tells me that the preparation of the tea is a costly and tedious affair. The tea trade commences now in May. People are bringing in their teas in small parcels of three or four pounds to the receivers or Hongs. Some of these Hongs have a hundred men or more employed to select and pack the teas. Hu has over a hundred. These men have to be well paid, as the work must be done smartly and well, so as to catch the market, and preserve its quality. In the first place the tea has all been sorted by hand and both ends of each leaf nipped off, leaving just the body of the leaf only to pass as first quality tea. This work is done by women whose nimble fingers manage to do a lot in one day, and at lower wages than men would do the work for. The careful selection and equal nipping is thus an important matter, but the proper firing is undoubtedly the most important of all. Careful packing is also an indispensable necessity in order to preserve the aroma of the tea on the voyage, as no amount of proper firing can preserve the quality unless it is also well packed.—*Overland China Mail.*

A LIBERIAN COFFEE PLANTER at Deli intends shipping to New York two tons of the produce as a trial shipment. This speaks well of the productiveness of the soil of that place for coffee. But we are looking forward with interest for the same staple from Johore; if the specimens of coffee beans, we have seen taken from H. H. Maharajah's plantation be a criterion, the soil must be quite as good as that of Deli if not better.—*Straits Intelligence*, June 14th.

PAPER bottles are now made on a large scale in Germany and Austria. The paper must be well sized. The following is said to be a good receipt for the paper:—Ten parts of rags, forty of straw, fifty of brown wood pulp. The paper is impregnated or coated on both sides with sixty parts of defibrinated fresh blood, thirty-five parts of lime powder, five parts sulphate of alumina. After drying, ten or twelve rolled leaves are coated again placed over each other, and then placed in heated moulds. The albumen in the blood forms a combination on pressure with the lime which is perfectly proof against spirits, etc. The bottles are made in two pieces, which are joined afterwards.—*American Cultivator.*

THE COCKCHAFER GRUB continues to commit serious ravages in the Lloyd Botanical Garden, at Darjeeling. It is said to be similar to the grub which has proved very destructive to coffee planted in *patana*, or grass land, in Ceylon. Specimens of the grub itself, and of the beetle into which it develops, have been sent to a specialist in London with a view to establishing the identity of the species, and discovering a remedy for the pest. In the meantime, if it appears in the garden again this year, the distribution of living plants to outsiders will be suspended, so that the plague may not spread over the district. If the grub should take a fancy to tea, it would be very unfortunate. Happily, it does not appear hitherto to have shown any partiality in that direction.—*Indian Agriculturist.*

DECADENCE OF LEAF-DISEASE?—We learn that on the estate in Madulsima where leaf-disease was first observed, fifteen years ago, (in may 1869) there is at present a coffee crop equal to 8 cwt. per acre. We trust this may be of good augury. It is true that in large portions of Dimbula, Dikoya and Maskeliya, corp is by no means in proportion to blossom. This is owing to the debility of the trees from the action of leaf-disease and the absence of manure. The fungus may, nevertheless, be decreasing in virulence?

A WRITER in a contemporary journal says:—"I discovered, many years ago, that wood could be made to last longer than iron in the ground, but thought the process so simple that it was not well to make a stir about it. Posts of any wood can be prepared for less than two cents apiece. This is the recipe:—Take boiled linseed-oil and stir in pulverized coal to the consistency of paint. Put a coat of this over the timber, and there is not a man that will live to see it rot."—*American Cultivator.*

RUBBER CULTIVATION IN JAVA.—A correspondent writing from Bantam, says:—"I have begun tapping my rubbers (*Ficus elasticus*); a three-year old tree gave ½lb. rubber at one tapping. It does not seem to injure the trees: only where the cuts have been made in the bark, young roots sprout out, but this, I am told by the natives, is always the case with *Ficus elasticus*. The Ceará seems to give more sap than the *Ficus elasticus*. I will report later on, on this sort, as my Ceará are not old enough for tapping: only one or two about 2½ years old have been tried, and they were full of juice."

DARJEELING.—Still no rain worth speaking of. The ground is as dry as a brick, and unless we have an inch or so of rainfall within the next week or so, I fear very much that matters will be rather serious up here. As it is, rice is selling at almost the same rates as in 1874, and the coolies are, consequently, a good deal pinched. There is, fortunately, no chance of anything like a famine up here, because the hill men can always get a "square meal" off jungle products of kinds. In some parts of the district the maize has sprouted, and this is just the time when a fall of rain does most good to this very important crop. Tea also is much retarded. There is a splendid "flush" all over the hill portion of the district, only just waiting for some moisture, and should a good fall of rain come soon, it will be a case of all hands on at leaf picking. Talking of tea reminds me that terrible mischief has been done to some new extensions in the district within the last few years by the larvæ of two varieties of cockhafer. The Lloyd Botanic Garden has also been suffering much from the same pest for several years past. These grubs remain underground in the larval state for three years before being developed into the perfect insect, and during the whole of that time they eat everything before them in the way of roots of plants, not excepting those of the *Ceronutane* Ferox, and grow enormously fat. It is really pitiable to see what havoc these pests can commit. It is apparently a thoroughly established fact that these *larvæ* only appear in places where the soil has been contaminated by green manure, such as the sites of old bustees; or, as in the case of the Lloyd Botanic Garden, where night-soil has been washed down by heavy rain. So far the only effectual remedy appears to be digging the ground thoroughly well when a young plant appears to be withering, to catch the perpetrator of the mischief and hand him over to the tender mercies of the *moorghies*. I am afraid to commit myself to an exact statement of the number of these *larvæ* unearthed in the Botanic Garden, but I am sure I am well within the mark when I put it down at over five millions within the last three years, and I know of one case in which over eighty thousand were dug out from a tea extension of less than twenty acres; and the other day I saw another extension where this pest had destroyed fully sixty per cent. of the young plants. Digging lime into the ground is being tried as a remedy, but it is impossible to say yet whether it will be successful or not. Leaf plucking has been commenced all over the district, but on a very small scale so far.—*Indigo and Tea Planters' Gazette.*

THE CACAO DISEASE.

The interesting discussion at the meeting of the Planters' Association (p. 90) makes us acquainted with the facts ascertained and the theories which prevail in regard to the disease which recently has assumed a virulent form on some cacao estates. Apparently we ought to say "some low country estates" for it is strenuously denied that it has affected plants on the older coffee estates at good altitudes. On the other hand, Mr. Ross denies its presence on the Matale estates and Mr. Vollar declares that on 1,000 acres of cacao under his charge there are not more than 1,000 trees showing signs of disease. He admits that there is an estate in Dumbara badly affected, but with reference to it he says: "You will never get cacao to grow where it is exposed to wind and the soil on which it stands is poor and shallow." Mr. Jardine, however, said that poverty of soil had not much to do with the disease. The estates chiefly affected seem to be situated between Polgahawela and Kurunegala and between the latter place and Matale, and the blight seems largely referrable to the abnormally droughty season which has prevailed. Should the disease turn out to be largely due to atmospheric causes and chemical action, without the presence of organic agents, insect or fungal, then the curious results will be established, that, while an excessively wet monsoon in 1882 proved injurious to vegetation in the higher mountain districts such as Dimbula, Dikoya, &c., the leaves being spotted and the stems and twigs mortifying and dying off, an abnormally dry monsoon proved equally injurious to the chief culture in lowcountry places in 1884, the effects, especially in the blackening and dying-off of twigs, being very much the same. From what is already reported there is every hope that the final result may be also the same, the recovery of health and vigour by the plants attacked. At one time on Abbotsford, in the monsoon of 1882, it really seemed as if the disease which had begun with the gums and spread to the cinchonas, would destroy not only them but the hardy tea also. The depression of those interested was in proportion Now in 1884, all the plants affected have shaken off the disease and under the influence of what at that elevation is a most genial season, tea is flourishing, beyond all precedent. With the return of normal moisture, we believe it quite likely the lowcountry cacao cultivators will have a similar tale to tell. We had strong reason to believe, that, besides the effects of persistent wind and rain, the trees upcountry suffered from the effects of an excess of chloride of sodium, from salt-storms, in fact, and we submit that Dr. Trimen in his investigations will do well to take special cognizance of the south-west monsoon wind as a bearer of more or less salt spray, sufficient largely to account for the blackening and dying off of branches of the evidently delicate cacao. On the seashore at Colombo, the doctor can see young coconut palms, with their foliage blackened as if, to use Mr. Jardine's phrase and repeat our own, "a blast of fire had passed over them." In his investigations Dr. Trimen will not forget his Abbotsford experience. Judging from the specimens of twigs and leaves of gums and cinchonas sent to him, he went to the estate with the confirmed impression that he would find the insects which had committed the mischief. He failed to find any as completely as we had done, and he decided that neither insect nor fungus had produced the mischief, but meteorological conditions. The case of the cacao plants which were enclosed in mosquito curtains for a fortnight, but the twigs of which blackened, seems to prove conclusively the effect of abnormal weather in producing chemical action in the plant juices and tissues. A gentleman tells us that on examining a blackened branch on an old tree in the Southern Province he founed traces of a borer having entered near the stem and gone towards the point. In the discussion at Kandy no idea of a borer was suggested, but only of flies so minute as to be invisible or of big juice-suckers too sparse to be loaded with the blame. We are by no means ignorant of the mischief which nocturnal insects can effect without making themselves obvious, and, of course, when maggots are found in the pods, then we *know* that insects have been at work. But the green fly or bug "Helopeltis Antonii" makes no secret of his presence and can be caught, as we saw in Java, in tens of thousands. As we have mentioned Java, we may again say that in the cacao plantation at Buitenzoorg we saw a large proportion of the pods black with "blight." Dr. Treub used that general term, suggesting neither insect nor fungus, but stating, that, in view of the liability of the red variety of cacao to attacks of this blight, the Government of Java at his instance, had indented for a supply of seeds of *cacao alba*, that very white variety which is found here in Ceylon to resist the blight. Now, while we know that all over South America, the West Indies and Java cacao is grown under shade, it is our duty to record the fact that the plantation where we saw so many pods black with "blight" was densely shaded with huge trees of *Albizzia moluccana*, for which it was claimed that its leaves gave shade from the sun-rays in the daytime and drooped at night so as to permit moisture to get to the ground. That growth under shade is the natural condition of the chocolate plant seems placed beyond doubt by what is stated by Mr. D. Morris in his recent work on Honduras. After showing that cacao of several varieties is indigenous in the forests, Mr. Morris goes on to state:—

> The wild trees in the forest grow under the shade of large overhanging trees in deep soil, and in rather moist situations. That cacao-trees, even under cultivation in the plains, require permanent shade, is very clearly indicated by the circumstances under which the wild trees are found. The cacao-tree never appears to such advantage, or thrives so luxuriantly, as when it occupies a cool, moist situation, in deep, well-drained soil; thoroughly sheltered from strong winds, and with moderate shade above. The Socunusco cacao, grown in the province of that name on the Pacific, is supposed to be the best cacao known, and little, if any, of it finds its way into foreign markets. This cacao is supposed to have been reserved, from time immemorial, for the use of the Royal Court at Mexico: and the drink or beverage prepared from it was highly appreciated by the Mexicans, with (whom it was held in religious veneration. As the trees have the same habit and characteristics as those of Caracas cacao, derived from the class *Cacao criolla*, the trees in British Honduras will, no doubt, be found to be the yellow-fruited variety of that highly esteemed plant. In *Forastero cacao* (the class of cacao chiefly under cultivation in Trinidad and Grenada), the yellow varieties are supposed to yield finer and better cacao than the red; and if these characteristics obtain in the *Cacao criollo* class, than we have in the Tabasco or Socunusco cacao of Central America, which, as shown above' is also a native of British Honduras, the finest quality of cacao which can be grown.

Mr. Vollar, who has charge of the largest extent of cacao cultivation, we suppose, in Ceylon, is strong in favour of wind-brakes for shelter and jak trees for shade, and he went so far as to say that the only traces, small as they were, of disease on the cultivation under his charge was where the shade of the jak ended. Nevertheless, we lean to the opinion, that, if rich soil in a well-sheltered situation could be found, cacao would do well without shade. The balance of testimony is in favor of shade, but N.B. that the shade used is generally an *Erythrina*, the foliage of which is never dense, and which is

entirely thrown off at certain periods of the year. If shade is essential, then very important is what Mr. Holloway says about the crotou, which yields a commercial product, gives shade and prevents the approach of insects. Rather too much seems to us to have been made of the fact that nurseries were badly affected. In nurseries the plants are unnaturally crowded together. At Buitenzorg we saw mature Liberian coffee trees almost free from the leaf fungus, while the under sides of the leaves of nursery-plants looked as if they had been electro-plated with copper. Then it is important to know that a dusting of wood ashes cured the nursery-plants. Ashes might do good to the older trees, if obtainable in quantity. Mr. Ross had shaded and unshaded coffee free from disease, while Mr. Vollar had no diseases except on exposed ridges. Disease seems to come and go with equal suddenness, which would favour the idea of atmospherical influences, unless insects or fungi can be caught in *flagrante delicto*, and evidence against either is as yet wanting. If the conditions present are poverty of soil and abundance of wind, while shelter and shade are absent, then, of coarse, disease followed by fatal results is to be expected. Local causes are evidently at the root of much of the disease which has caused alarm and led to exaggerated reports. No plant can be largely cultivated which is not liable to visitations of pest and disease, and cacao certainly seems a delicate plant. But we see no reason to suppose, from the evidence hitherto adduced, that the disease which in this abnormal season has attacked cacao in the lowcountry of Ceylon is destined to be other than temporary and evanescent.

CACAO DISEASE IN CEYLON.

The following discussion to the subject of cacao disease in Ceylon took place at a general meeting of the Planters' Association of Ceylon on June 28th :—

The HON. J. L. SHAND: —I should like to refer, Mr. Chairman, to a matter which has given me a great deal of anxiety lately. It is not on our programme today but it is a matter of such very serious import, and especially as very exaggerated reports have gone about, that I think no time should be lost in bringing it forward. I refer to that fell disease which has attacked the cacao trees throughout the country. I see gentlemen here who are interested, the most interested, in cacao ; and from what I have heard these reports have not only been very much exaggerated but in many cases are almost entirely without foundation, and I shall be very glad indeed if some of those gentlemen who are interested in cacao can tell us something reassuring which shall go forth as a part of our proceedings, and which will, I think, have good effect throughout the country.

The CHAIRMAN called on Mr. Vollar, as one of the largest cacao-growers present, to say a few words on the subject.

Mr. VOLLAR said he would only say that he had heard very strong remarks about a large quantity of the Dumbara cacao dying out, but he had got 1,000 acres under his charge at present, and out of that he had only about 1,000 trees affected with fly, and those parts which were effected was where no shade existed. He found that a good deal of the damage which was done to cacao by the fly was on unshaded land ; and he thought, that, where land had been opened where there was no shade, the ravages of the fly were far more severe. On his estate he had only about 1,000 trees affected altogether, so that there was practically none. In Dumbara there was one estate which was very badly attacked which was said to be by fly, but he hardly thought it was. He thought there were other causes than fly to which it would be attributed : the land was poor, the soil was dry and it was greatly affected by the wind, and they could never get cacao to grow where land was poor and the soil shallow. (Hear, hear.)

Mr. JARDINE said he had not had much experience of other districts but round about Polgahawela and Kurunegala and in those districts he was bound to say that some estates recently have been very badly attacked by something, a fly or an insect of some kind. Mr. Vollar had said that unshaded estates suffered most. Well most of the estates in that district happened to be without shade, and it was possible this want of shade had something to do with it. Another thing which he thought must be taken into consideration was the unusual season we had had this year. We have had a very long and protracted drought and we had not had our usual monsoon rains, which had made cacao suffer and had weakened the trees, and it is because the trees have lost their stamina that the disease has appeared so virulently. He had seen the disease before as far back as 1881 : he remembered a patch of 20 acres which was as badly attached as any place now. He thought at that time that that cacao was doomed and would never recover; but he was glad to say that in a few months the trees recovered, were reclothed with new wood, and for three years they gave very good crops. (Applause.) This year again that field has suffered more than any other portion of the estate, so that there might be some local causes at work. It was quite possible that particular localities are liable to this attack than others, but the bulk of the estates really have suffered very little indeed. On another estate he had under his charge, there was an open portion of the estate where fly seems to be regularly domiciled all the year round; the rest of the estate is very free, and it is seldom that young shoots are attacked. He must however say that he thought this disease was one that might be serious. He did not say that at present it was going to cause the destruction of their cacao, far from it, he thought the contrary; but at the same time it was a serious thing, and one of which they ought to find out the real cause. At present they were rather in the dark as to what fly caused the mischief. He had collected ten or twelve different kinds of insects that attacked the cacao, others attack the leaf; some are sap-suckers, some of them most formidable-looking creatures which would extract the sap, not only of the very young wood, but even of the old wood ; but these were so few in number he could not attribute to them the sudden cause—it was a most sudden thing—the sudden destruction which comes over young cacao branches. They saw that today these trees were putting forth young leaves and young branches, and two days afterwards they looked as though a blast of fire had passed over them. A few insects could not do that ; they must be in very, very large numbers, and they could not find these insects. For months, perhaps, three or four young flushes of wood come out, they set all right and there is no more change; then suddenly they learned that all the young flushes and the young wood had been destroyed somehow. The trees of course naturally recovered, but these repeated attacks must weaken them. He certainly could not find out what fly it was ; it seemed to be some minute insect which came in vast numbers, or they could not go over an estate of 200 acres in one night and destroy all the young tender shoots; where these insects got to, was what puzzled him. He certainly did not say that the disease was going to kill out these cacao, far from it, it is only in certain spots that it is very bad, but at the same time it must cause to all who are connected with cacao, a great deal of

anxiety. One thing he had observed was that what was called Carácas cacao which was really Trinidad cacao, was almost entirely exempt, it seemed to have an immunity from this disease. He had thousands of these scattered about amongst the coffee, and, whilst the other trees were very badly attacked, these were vigorous and strong and had not the slightest signs of disease, and therefore it became a question for future cultivators whether they would grow red cacao or this more hardy *forastero*. This was all the information he would give them on the subject.

Mr. ROSS said, speaking for Matale, he might say the disease did not exist there to his personal knowlege. It certainly did not exist on the acreage coming under his inspection, where, his experience was similar to Mr. Vollar's. He had heard of its existence in Matale on a small scale and his informants had told him that it was only on exposed ridge. His experience with regard to cacao was that wherever there was suitable soil and a sheltered situation nothing could get over it. With regard to the appearance of the trees being as Mr. Jardine had put it, as if a blast of fire had swept over it, he had seen that on a ridge of land where the jungle had been cleared. Before the shelter was cut down the cacao was vigourous and there was not the slightest sign of the disease, but it had this appearance very shortly after.

Mr. JARDINE :—I wold ask Mr. Ross if this part of his estate is under shade.

Mr. ROSS :—It was, but it is not now: the jungle there has been cleared.

Mr. JARDINE :—It was under shade before; and now it is cut down you have no disease ?

Mr. ROSS :—We have a large acreage under shade and some exposed.

Mr. JARDINE :—You cannot say from that that the shade has prevented the disease ?

Mr. ROSS :—I cannot, we have cacao shaded and unshaded.

Mr. VOLLAR remarked that he did not attribute it at all to the fly. He knew a man who put mosquito curtains round the trees and fumigated the trees and the same apperance was on the trees a fortnight after.

Mr. CLARKE said he might mention that on an estate above Matale, on which there was no shade, he hunted for the disease and only discovered it on two trees. The superintendent said there was more on the younger saplings but he failed to find it.

Mr. MELVILLE WHITE said he endorsed Mr. Vollar's view entirely. His experience of cacao was not great —he had 50 or 60 acres, He had observed it as much as he could, and his experience was that where shade has been cleared off and the soil is poor this appearance comes, but wherever coffee is good, which is an argument that the soil is good, there cacao is unaffected. He knew many superintendents in Matale had searched very carefully for this fly ; and on one estate, where there was considerably over 100 acres, two superintendents were busy for two or three hours looking for this fly, and they only succeeded in finding one, and he thought it was quite impossible for one fly to have done all the damage. He did not think the disease was known in Matale : there was only a few individual trees affected, and, as far as he had been able to see, where shade was more considerable the disease was less apparent and where shade has been cleared off there the disease was virulent. There had been no trees killed with him, and he had heard of none in Matale.

Mr. HOLLOWAY said he had a few remarks to make with reference to cacao. He had found the same as Mr. Vollar that cacao under shade was certainly better than without shade. Especially was this so under crotons. Croton seemed to keep the flies off, and he found of all shade trees it was the best, because it kept the disease away and was a product too. He certainly recommended crotons to be planted where cacao was, and with reference to the varieties of cacao he had found the *forastero* a much hardier tree. He kept four species of trees on his estate and he found from the Trinidad cacao that evidently some of the pollen had been taken from the other trees, and the effect of it upon the red cacao was to make the tree variegated.

Mr. WHITE :—One question I would like to ask. Mr. Jardine says most of his cacao was planted by itself ?

Mr. JARDINE :—No: the bulk of it was planted in Liberian coffee. I would just like to elicit one other piece of information. I would like to ask Mr. Vollar does he mean shade or shelter ? Is his cacao under shade or is it simply sheltered from the wind ?

Mr. VOLLAR :—We have a shelter from the wind ; for shading this portion of the estate jack trees are planted here and there. We have parts however which are open to the south-west wind, and it is on these ridges we have about 100 trees affected, and about two acres are affected by the fly where we have no shade. It is a very strange thing, but where the jack-tree shade commences, there the fly stops.

Mr. T. N. CHRISTIE said he knew very little about cacao, but on the occasion of a recent visit to the cacao districts he was simply horrified to see the hold this disease had upon the trees, and, notwithstanding what had been said about shade and soil, he had seen that nurseries in the best soil and under shade were just as bad.

Mr. JARDINE said he could corroborate that from his own observation. On an estate not far from his there was a nursery of red cacaos and a nursery of *forasteros*. About 90 % of the red seed was destroyed, while of the *forasteros* not a single plant was touched, and they were growing side by side.

Mr. ROSS said he must say his experience with regard to nurseries coincided with Mr. Jardine's but after treating them with wood ash the plants are quite vigorous. He could not make out what caused the disease.

Mr. JARDINE said he would attribute it to nothing else but an insect, and the marks of it would be seen on the plants.

Mr. WHITE thought it strange that they could not see the fly at all.

Mr. JARDINE imagined that it was a very minute insect.

The CHAIRMAN :—This subject has been already referred to the Government. A firm in Colombo found that properties under their charge had suffered to such an extent that they deemed it so important that they addressed the Government and the Government acting upon their suggestion and express wish have deputed Dr. Trimen to examine the particular estates. I won't mention names because under these circumstances it is better to speak only of facts themselves. Regarding one property which was the especial subject of the correspondence I have alluded to I have since been told by gentlemen on properties adjoining and who were therefore very competent to judge, that there was reason for thinking blight was responsible for the very severe distruction which had taken place there. Of course I am not called upon to state what these conditions were but they confidently assured me it was to those special conditions the severity of the attack was due. My own personal attention was directed by Messrs. Bosanquet & Co. quite recently to this matter, and since that time I have made several visits to cacao estates with the result that I am satisfied, that, at least, in several, I may say the majority of cases, the so-called disease is one which we have been familiar with for some time but attributed to wind. That this had been caused by wind was in the first place not questioned and un-

doubted and therefore no enquiry was made. When time had elapsed that was further confirmed by the rapid recovery of these very trees which were affected. But on several estates I have looked to where it has been fairly traced to the insect, shows we were mistaken in attributing it to wind. Wind may have done its part, but there were, however, pests besides. The important facts I had gathered tend to confirm what I have heard today that where cacao was not vigorous there blight had been very destructive indeed, but in places where cacao was vigorous there the blight had a temporary and trivial effect. It had blasted the points of the branches very much as wind will blacken the points of coffee, but these have been very speedily replaced by more vigorous shoots. On one estate in particular I was taken by the manager who does not reside on the estate and who had not visited it for a week. I was taken down to see what he called the worst place, and he was astonished at the change, which had come over the place in that week, and there appeared to be every prospect of its recovering as it had done on former occasions. One of the largest cacao cultivators in this country, who is not here today to speak for himself, has expressed his opinion to one of the managers with whom I have been conferring, that he believed the blight would severely affect his estates which were poor soil, especially those where there was very shallow soil and where cacao was not very vigorous; but the estate he himself had charge of was a remarkably fine one and he had very little anxiety on the subject. I think we should wind up the subject by appointing a committee who will confer with Dr. Trimen, who will very gladly give all the information he may obtain in the meanwhile. With regard to the insect it is known to be one of a tribe which commits its depredations in the night; it is one of those nocturnal insects of which we have many examples within our knowledge, and therefore it is not quite so unaccountable as some think. I propose that a committee be appointed to take evidence and confer with Dr. Trimen and report when they have sufficient information on the subject.

Mr. ROSS remarked, that, notwithstanding what had been said, he still believed it to be the effects of wind, because he had himself examined the trees and could find no trace of perforations on the branches.

MR. CLARKE:—I should like to ask Mr. Christie one question whether the estates he referred to were good soil or not.

Mr. CHRISTIE said most of the estates were in the lowcountry where the soil was not so good, but, if the drift of Mr. Clarke's question was to indicate that exposure and poverty of soil were the causes, he could not agree with him, because there was the fact of these nurseries where there was undoubtedly good soil and which were carefully sheltered and which had yet got the blight.

Mr. JARDINE:—I must give it as my opinion that poverty of soil has very little to do with it, for I have got cacao on the finest soil you can get in Ceylon that suffers with the disease.

MR. CLARKE:—I think this disease is chiefly down in the lowcountry and not in the old estates where the soil is good, and cacao there does not seem to be affected by the disease. As this discussion will probably go home it will alarm old proprietors who have been spending money on the old estates, on cacao, and they will imagine that this disease is to be serious. I think it should be stated that it is not on these old estates, but in the lowcountry that the disease exists.

Mr. BLACKETT proposed that Messrs. Jardine, Ross and Vollar be appointed a committee to confer with Dr. Trimen.

The Hon. J. L. SHAND said he had very great pleasure in seconding that. They were indebted to the gentlemen who had given them their opinions, and the most gratifying feature of the discussion was to find that they had so many cacao planters amongst them. (Applause.)

Mr. GIBBON thought a great mistake had been made in opening land without any shelter or wind-breaks. He was almost certain that in the case of the great bulk of the land which had been affected it was from want of wind-breaks. He did not think the shelter of coffee was sufficient. He did not think cacao planters would be wise in neglecting to have wind-breaks all over their estates. He did not believe much in shade but wind-breaks were most necessary.

Mr. BLACKETT's resolution was then put and unanimously agreed to.

Specimens of prize tea from the Calcutta Exhibition, official catalogues, malt coffee and mortice work for tea boxes made by machinery were laid on the table through the courtesy of Mr. Capper for the inspection of members.

The proceedings then terminated, the number of members present at the close being about half-a-dozen, the majority having left at the conclusion of the discussion on the Cooly Wages Ordinance.

CACAO AND BLIGHT IN THE DUMBARA VALLEY.

(*By Our Reporter.*)

The alarming rumours which have been industriously circulated of late, that a terrible pest was decimating the cacao estates in Dumbara and other parts of the country and was doing on an even larger scale what *Hemeleia vastatrix* has done on coffee estates, have naturally created the greatest anxiety in the minds of planters, as many estates are now being planted up with the product in question. For the purpose of testing the accuracy of these statements I have just paid a visit to the most important estates in the Dumbara valley, and I am very glad indeed to be in a position to give a contradiction to these rumours. Cacao blight practically does not exist in the Dumbara valley, or, at any rate, exists to so small an extent that there is no reason for any alarm at present, though, of course, it must be carefully watched. The report of the Committee appointed at the P. A. meeting on Saturday to investigate this subject in conjunction with Dr. Trimen will of course be looked for with great interest, as it will carry the weight of experienced and learned men, and there is every reason to believe that it will be of a reassuring character; but in the meanwhile some account of the present condition of cacao in Dumbara may not be altogether without interest.

Accompanied by a planter whom the alarming reports of cacao blight had reached and who in consequence was on his way to the Polgahawela district to ascertain for himself the real position of things in that part and piloted by Mr. H. J. Vollar of Pallekele estate, the oldest cacao estate in the country, I yesterday inspected a large acreage of cacao, with the result, that, instead of finding blighted and withered trees, as the reports which I had heard had quite led me to expect, I saw field after field of vigorous, healthy trees, a little the worse for the unusual drought they have experienced, it is true, but nevertheless in a most promising condition. And this drought, I think, is the keynote for the scare which has been caused. The season has been a most abnormal one, not a fiftth of the usual rainfall havin

been registered in this district. Dumbara knows nothing yet of the south-west monsoon, except a few showers lasting perhaps ten minutes each, which have fallen within the last day or two. The total amount of rain which has fallen in this valley since January has been only 11 inches. At least a normal amount of rainfall is essential to the proper growth and development of the cacao plant, and it speaks something for the vitality and healthiness of the trees that they have stood the prolonged drought so well. As was pointed out to me, anyone looking casually over the estate, and seeing on the tops of the trees dead shoots entirely devoid of leaves, might easily run away with the impression that they were the work of blight, now that the scare has been started, but investigation will show that this is not a cause for any alarm and is indeed but the perfectly natural procees of "dying back" which the cacao trees in common with other trees undergo. On any common jungle tree the same thing can be seen: the tree cannot always grow up, and the dying away of the topmost shoots is in itself perfectly natural. That this has nothing to do with the disease is evidenced by the fact that the tree loses none of its vitality, and some which were pointed out to me were covered with pods and young shoots. Here and there a young tree will be found completely dead, but a satisfactory explanation of it can be found without making it a consequence of the disease. What is more common on a tea estate than to find here and there a plant die off, perhaps from drought, perhaps because it is a naturally weak plant, or there may be some fault in its planting out.

As to the nature of this new pest there is some difference of opinion, but I think there can be little doubt that it is an insect pest, and therefore not so terrible an enemy as the dreaded fungus. It is supposed—and in fact may be said certainly—to be the work of *Helopeltis Antonii*, a fly which "cometh like a thief in the night" and attacks the tender shoots of the tree. Trees which have been so attacked, though apparently healthy enough one day will be found shrivelled and dead the next day with minute perforations visible on the young shoots and leaves, and this always takes place in the night. But a most important factor in the case is the fact that healthy trees are not attacked. I can confidently say that as far as the Dumbara estates are concerned it is impossible to find a healthy tree which has suffered from the pest. On one estate in Dumbara, disease is very bad; but what is the reason? Why, one or more of the most important elements in successful cacao cultivation is wanting and the trees are naturally unhealthy and prone to disease. Cacao is a deep feeder, and it is impossible to grow it successfully on a rock covered by six inches of soil; it also requires a good soil, and it will not grow in a hard soil of which iron is a large component; it is likewise a delicate plant which cannot stand exposure to the wind and therefore will not grow on bare exposed ridges, and, what is perhaps of more importance than any, it requires plenty of rain; and yet I have found every one of these conditions absent, with the result that trees have died and a terrible pest has been blamed. A theory which I heard expounded by an experienced cacao planter is that, if some essential element of cultivation has been neglected or is wanting, the tree becomes unhealthy, and in this state its sap is sweetened. The sweet sap attracts the fly which bores into the young shoots to get at it, and, having extracted its vital principle the tree rapidly dies. This of course is only a theory, but it is a very reasonable one and one which might very well be subjected to scientific investigation. It is at any rate borne out by the fact that in a healthy state the trees are not attacked by the insect.

Most planters I have met insist upon the necessity of shade. Mr. Holloway has a characteristic proposal, which at any rate has the merit of being novel. It probably would not have occurred to anyone but Mr. Holloway that croton made a good shade for cacao trees and the particular merit he claimed for it at the P. A. meeting was that it was profitable to cultivate crotons, though I imagine there are not many planters who will endorse Mr. Holloway's opinion as to its suitability as shade for cacao! Jak-tree is a favourite cacao shade and answers its purpose very well. Mr. Vollar believes in planting shade at the same time as the cacao is planted and allowing both to grow up together, as young plants will not grow so well under shade. The superiority of the trees grown on good soil over those planted on hard or poor soil is very apparent, and to plant cacao where coffee will not grow is simply absurd.

Several remedies for the blight have been suggested. Pure kerosine oil poured over the tree prevents the fly from renewing its attacks on it, but, as it is almost certain to destroy the tree, the remedy is worse than the disease. Pruning the parts attacked has been tried but with little success, the insects simply going to another part of the tree; and this lends colour to the theory that the plants attacked are from some defect in their cultivation susceptible of attack and that healthy trees will not suffer. The most effectual remedy for it in my opinion is to root out all the cacao where it has been attacked and plant something else in its place, for the very fact of its having been attacked shows that the soil or locality is not good for cacao. Some very fine cacao trees 30 years old were shown me, on Pallekele, covered with young pods, and indeed all the cacao on this estate is exceptionally fine. One or two trees which had been attacked, the only ones we could find, were examined, and in every case it was shown that either the trees were in a position where they were exposed to the full power of the wind or else they were planted on poor or insufficient soil. The blight is said to be very virulent in the Polgahawela district, and it would be altogether premature to assert that it is of no consequence, or even that it will not be yet another trouble heaped on our long-suffering and sorely-tried planters, and it will, therefore, require the closest watching and the strictest investigation, but at the same time it is really not necessary at present to take the extremely alarmist view of it which some people take. Of course any theories or conclusions of mine carry no weight, but it certainly does seem to me that people whose estates offer all the elements necessary to success, good soil, shelter, &c., need not be afraid of their cacao trees, for if the trees are healthy they will not be attacked by the fly.

Turning to coffee for a moment, there are some magnificent crops to be seen in Dumbara and the prospects with regard to our old staple are much brighter this year than they have been for some years past. Fever is very prevalent amongst the coolies: on one estate yesterday only six turned out at muster, and on another some 60 or 70 were in the hands of the doctor. Drought is no doubt the cause of this, and rain is anxiously looked for. Probably a fortnight's rain would wash cacao-blight away.

Export of Ceylon Tea.—A writer in the *Indigo and Tea Planters' Gazette* states:—"Then a new factor has now to be taken into account in Ceylon, and we note they expect to have ten millions for exports this year." The "note" was very far out, for in the season which will end on 30th September we do not expect our export of tea to exceed one-fourth of the quantity mentioned.

CORKS AND CORKWOOD.

There exists in the art of bottling no more prominent factor than the cork.

And yet it is extremely doubtful if one person in ten—aye, one in a hundred—of all those who are called upon to handle this useful article, either in connection with bottling or otherwise, has any definite idea of its history, the mode of its culture and preparation, or the multitudinous uses which it is called upon to serve.

To such as are enlightened upon the subject it must always be a matter of wonder what the world did before corks were invented.

Did the ancients have bottles? If so, with what did they seal them? for it is difficult to imagine any article that could fully supply the place of cork.

A glance, therefore, at this subject, viewed from a historical and agricultural standpoint, may not prove uninteresting reading to those whose interest our paper is endeavoring to serve.

First, let us glance at the history of cork.

It is certain that its culture and use was familiar to the ancient Greeks and Romans, though it was not largely employed by them as a stopper. This was owing to the peculiar nature of the bottles employed, which were made of leather, or often of the undressed skin of the goat or kid.

The method of making these bottles was to strip the skin of a goat from over the neck of the animal, leaving it otherwise nearly without holes, such as there were, being formed by the legs, and were easily closed. These primitive bottles are used by the Arabs to this day.

In the form of stoppers for general use, cork were introduced toward the end of the sixteenth century, since which time the industry has not ceased to grow in importance.

The bark of all trees consists inwardly of a parenchymatous, or soft cellular tissue, and outwardly of a harder, woody, tubular tissue, the latter generally being more abundant. If the growth of the pareuchma be prolonged and rapid, it will assume a more or less corklike character, as is true in the case of some of the elms, the common oak, and many other trees.

This peculiarity is developed to an exceptional degree in one species of oak, which has been named, from this circumstance, *Quercus suber;* it is the bark of this tree which constitutes the cork of commerce.

The cork oak is an evergreen, growing to the height of about thirty feet; its acorns are edible, and resemble chestnuts in taste. It does not require a rich soil, but, on the contrary, seems to thrive the best on poor and uncultivated ground.

It is principally found in France, Portugal, Spain, Tuscany, the island of Sardinia, and on the African coast bordering on the Mediterranean.

The cork used in this country comes entirely from Spain and Portugal—the provinces of Catalonia and Estremadura in the former, and Alentejo in the latter country, furnishing the most abundant supply.

The Portuguese cork is inferior to the French in quality, but superior to the Italian, being lighter and whiter. Sardinia produces a kind easily distinguished by its color and weight, being pinkish hued, and heavier than many other varieties. It is considered by the English the best variety which can be obtained, but little if any of it comes to the United States. In 1861 it was reported that cork forests of Sardinia and Corsica had been in a great measure destroyed by improper working; but this report, like the annual rumored failure of the peach crop in Delaware, seems to have made little difference in the supply.

France produces the finest grades of cork, especially in Languedoc province and the environs of Bordeaux. The peculiar velvet cork, so esteemed in the bottling of champagne, is the production of these places, and is becoming very scarce, it being feared it will, in time, become unobtainable.

Africa produces large quantities of cork, but of an inferior grade, although the soil and climate of its northern countries seem peculiarly favorable to its propagation. This is especially true of Morocco and Algiers. The causes of this are to be found in the uniformly high temperature and profuse nightly dews, while the dry, warm, open hillsides are covered with a sufficiency of light soil, peculiarly adapted to the growth of the trees, which attain to a larger size here than elsewhere.

There are said to be 2,500,000 acres of cork forests in Algiers alone, of which about 300,000 are utilized. It is said to be capable of producing as much cork as all the rest of the globe, if the inhabitants could but he persuaded to remain peaceable, and give their attention to agricultural pursuits.

In 1859 an attempt was made to introduce the cork oak into the United States, Portuguese acorns being planted, with this end in view, in Wayne County, Miss. All grew, the largest trees, eleven years later, measuring thirteen feet in height, while the trunks had attained a diameter of eleven inches in thickness, the cork bark being more than an inch in thickness. In 1872 the planting of cork trees was attempted in southern California, but with what success does not appear.

Among the conditions necessary for successful cork culture, climate and soil are of the foremost importance.

In the Mediterranean basin, where it is indigenous, the tree favors altitudes varying from 1,600 to 3,200 feet. It does not flourish beyond 45° north latitude, and the minimum temperature must not be less than 55° Fahrenheit.

It grows best on southerly slopes, which afford a freer circulation of light and air than do flat lands. It requires abundant sandy soil. Planting is usually performed from seed; as a rule the large, sweet acorns developing into the best trees, which yield the finest cork, the small, bitter acorns producing trees of a coarse and inferior nature.

The most approved method of planting, and that which is employed in France, Spain and Portugal, appears to be the furrow or "hill" system, which consists in sowing the acorns twenty to forty inches apart, in a furrow between two or more grapevines, placed at from five to seven feet apart. The sowing and planting are conducted simultaneously, the vines affording the shelter which is so necessary to the cork tree during its early growth. The young trees are thinned out as required, so as to afford abundance of air and light to each. About fifty trees to the acre are recommended by the French cork producers, and the production is about eighteen pounds to each barking of she tree.

The distinguishing feature of the cork oak is that the parenchyma forms the mass of the bark, while the contrary is true with nearly all other trees. In the earlier state of its growth it is much more elastic than it ultimately becomes, owing to its containing, in the first instance, a large proportion of woody matter. The outer casing of the bark is formed during the first year's growth, and does not subsequently increase; but the pareuchyma, or inner bark, continues to grow as long as the tree is alive.

In consequence of this phenomenon, the pressure of the growing inner bark beneath forces the outer shell to split and peel off in flakes. The substance thus shed under natural conditions is known as "Virgin cork." It is very coarse and of woody texture, greatly resembling the bark of the California live oak in appearance. Its uses, from its coarse nature, are very limited.

The removal of this outer bark from the tree is, fortunately, when performed in a judicious manner, unattended with any evil consequences to the tree; on the contrary, the operation seems to hasten and assist the growth of the bark, improving its quality, and at the same time the tree grows more vigorous, and attains greater longevity, trees which are regularly barked being known to live to the age of one hundred and fifty years and upward.

The age at which the first stripping may be attempted varies with the locality, from fifteen to thirty years, the former being the most general.

The yield much resembles the naturally shed virgin cork, and is commonly included under the same term. Subsequently the barking is repeated at intervals of eight and ten years, the quality improving on each occasion. The second crop is also still too coarse for any but inferior uses.—*Independent Journal.*

CHARDUAR RUBBER PLANTATIONS IN ASSAM.

[By GUSTAV MANN, Esq., Conservator uf Forests, Assam.]

I have the honour to submit a report on the Charduar rubber plantations in the district of Darraug, including its past history, the results gained, and a sketch of my views as to the future treatment and extension of that plantation.

2. The past history of rubber plantations in Assam, and,

fer the matter of that, in India, dates from the year 1872, when Mr. James Collins was charged by her Majesty's Secretary of State for India to prepare a report on the caoutchouc or Indiarubber of commerce, the plants yielding it, their geographical distribution, and the possibility of their cultivation and acclimatisation in India. The only rubber-tree indigenous in India (*Ficus elastica*) is noticed on pages 19 to 21, 32 to 39, and 48 to 54 of that report.

3. The numberless uses to which caoutchouc is applied, the daily-increasing demand, and the very high price paid for it, as well as the total absence of any other product, whether raw or manufactured, that could be used as a substitute, with the sole exception of gutta-percha, which is still more expensive than rubber, had for years attracted the attention of thinking men to this matter, and Mr. Collins's report was therefore welcomed by all, and particularly so by men who took an interest in the development of the resources of India.

4. This report was largely circulated by Government in this country, and the attention of Local Governments was directed to the necessity of protecting the trees which yielded this valuable commodity because it had become quite evident that the caoutchouc trees were being recklessly destroyed in all parts of the world, and particularly so in Assam, which is, so to speak, the only province in India where caoutchouc trees grow, and the experimental cultivation of the indigenous rubber tree (*Ficus elastica*) was accordingly ordered in May 1873 by his Honor the Lieutenant-Governor of Bengal. But by the time these orders reached the Commissioner of Assam, the season was so much advanced, that but little could be done that summer, because there was only one small forest plantation with a resident forest officer in existence at that time, and this was at the Kulsi river, which is not as favourable a locality as the Charduar, in the Darrang district. In the latter district forest work had not been started, and, consequently, the first commencement in the present Charduar rubber plantations was not made until the next cold season. A detailed account of these first attempts at planting rubber will be found in paragraphs 80 to 114 of the Assam Forest Report for 1873-74.

5. A particular impetus was given to this work by the complications and difficulties that had arisen at about the same time in the proper management of and control over the Indiarubber trade in this province, brought on by competing speculators, which had necessitated an order from the Supreme Government that the operations of the Forest Department should be limited to conservancy and reproduction of the rubber trees in certain well-defined areas, and to the collection and manipulation of the produce in such limited areas through their own agency.

6. This order of the Government of India was repeated in 1876, and has been acted up to until now: all work in the way of rubber plantations is based on it, and, what is more, the experience gained in the twelve years that have elapsed since the issue of that order has made it clear that the effectual protection of selected areas, *with naturally grown rubber trees on them*, is next to impossible, on account of the localities where these trees grow being, generally speaking, very inaccessible, and the unequal way in which these trees are scattered about in the forests, as it would mean the protection of enormous areas to ensure anything like the present export of rubber from Assam, and this in turn would mean the employment of very large establishments to watch over the forests, because rubber is so very portable, and its removal not necessarily confined to roads or tracks, rivers, and so forth, as is the case with timber, and the cost of such establishments would altogether exceed the advantages arising from the rubber trade. This simply reduces the whole question of permanently keeping up the export of this valuable product from India to making plantations of the tree that yields it.

7. In April 1874 the Government of India called for a special progress report on the caoutchouc plantations in Assam, which was furnished with my letter No. 23A., dated the 27th May 1875, forwarded by order of the Chief Commissioner to the Government of India with letter No. 1,305, dated the 7th June 1875, and subsequently printed and circulated with the Government of India, Department of Revenue, Agricultural and Commerce (Forests), letter No. 22, dated the 31st August 1875. The efforts made up to that time in the way of planting caoutchouc trees in Assam, and all information regarding the yield of caoutchouc trees then available, have been fully stated in that report, so that there is no necessity for repeating it now; the views expressed by me at that time I hold still in all the main points, and the progress made in planting and the results gained have been recorded in the Annual Forest Reports for Assam up to date, as quoted, so that there is no necessity for repeating this either here, beyond pointing out a few of the main orders bearing on the subject, the chief occurrences which have taken place, fresh experiences gained, and changes adopted in the management:—

Report of 1874-75,	paragraphs	250 to 256 and 272-306.
„ of 1875-76,	„	65 and 68-77.
„ of 1876-77,	„	83 and 96-110.
„ of 1877-78,	„	106 and 122-131.
„ of 1878-79,	„	111 and 127-136.
„ of 1879-80,	„	125-127 and 146-151
„ of 1880-81,	„	113-118 and 137-145.
„ of 1881-82,	„	110-115 and 136-142.
„ of 1882-83,	„	77-78 and 83-85.

8. The Charduar plantation has, as was maintained from the commencement, proved in every respect the best locality in Assam where the rubber tree has been planted. The land, it is true, is not high, and so we must, no doubt, have some area planted on higher ground, if for no other reason than to enable us to make comparisons. This is to be done at once on the high land immediately to the west of the present plantation, as the Chief Commissioner has sanctioned an extension of 200 acres. The present area under cultivation is fully stocked, containing 12,511 trees; they have been planted at 25 feet apart in the lines, which latter are 100 feet apart. This is double the number of trees that was planted on an acre at the commencement. The eldest trees are about 30 to 40 feet in height, and a few from 45 to 50 feet, but this cannot be put down as the average growth of *Ficus elastica* in ten years, since half this time, and longer, these plantations were entirely experimental, and everything had to be learned, as, for instance, the first trees were all raised from cuttings, which mode of propagation has entirely been given up since the trees raised from seed have proved much hardier and faster-growing, and as to the planting of rubber seedlings high up in the forks of other trees, this also has almost entirely been given up, because such trees in most instances did not make more than a few leaves in the year, and it would, as a matter of course, be out of the question to plant rubber trees where they would take a century to become large enough for tapping, when such trees can be grown in a different way in one-fourth this time.

9. On the other hand, it has been found that trees planted on small mounds of earth, 3 to 4 feet in height, grow very much better than if they are planted on ordinary level ground, and this plan has therefore also been adopted, although it adds considerably to the cost of making these plantations, but the faster growth of the trees amply compensates for the higher expenditure.

10. The method of planting adopted from the beginning has been to clear lines from east to west through the forest for the young trees a hundred feet apart; the width of the lines is 40 feet, so that a broad strip of forest 60 feet wide is left standing between these lines, to ensure the utmost amount of moisture in the atmosphere for the young rubber trees. At first the lines were only cleared 20 feet broad, but it was found after a few years that these closed up very soon, and thus retarded the growth of the young trees by shutting out the requisite amount of light. However, the widening of the lines also brought about the faster growth of the scrub in them besides that of the rubber trees, and mere money, time, and attention has in consequence to be spent, especially in the rainy season, on these plantations than had at first been anticipated; but the greatest and most costly difficulty that had to be overcome was the effectual protection of the rubber trees against deer, which during the first few years constantly bit off the young plants, and, where they were not entirely ruined by this, they were so much injured and retarded in growth that a considerable increase in the expenditure on these plantations had to be incurred on fencing to prevent it. But for the future this expenditure will not be necessary, since it has been found that saplings 10 feet and more in height can be transplanted without difficulty and with prefect success, and if such saplings are tied firmly to stakes, the deer can do little or no damage to them.

11. The efforts made to interplant with timber trees

besides the rubber so as to obtain a yield of timber in addition to that of caoutchouc, have up to the present met with but partial success in the Charduar plantation, but there is no reason to doubt that this will soon improve as the officer in charge gains more experience; in the rubber plantation at the Kulsi, in the Kamrup district, this work has been most successful.

12. The total area of the Charduar caoutchouc plantation is now 892 acres, and has cost R64,351, or R72 per acre. This is abnormally high, since much of the work during the first five years had to be done twice over, and sometimes oftener, because the planting of caoutchouc trees was new, and everything had to be learned and found out by experiments, which naturally took some time. But matters have changed in this respect. We know now what we are about, and the officer in charge of this work, Mr. T. J. Campbell, has estimated the cost of the extension which is at present being carried out at R9 per acre, to which another R6 for subsequent cultivation and clearing should be added, bringing the cost, including everything, up to R35 per acre.

13. Besides the experimental nature of the work, to which the cost of R72 per acre of this plantation must to a great extent be attributed, we have also prepared extensive nurseries, covering an area of about 23 acres, and containing some 184,000 plants of different sizes, which is sufficient to extend the plantation by 200 acres per annum for the next 15 years, or a square mile per annum for the next 5 years, if desired, and these nurseries have been so planted that, if for special reasons it is considered advisable not to extend the plantation at any particular time, the trees can be kept almost stationary for 15 to 20 years, without becoming less suited for transplanting—a particular advantage enjoyed by *Ficus elastica* in common with other semi-epiphytes as compared with ordinary trees.

14. These extensive nurseries were got up in accordance with the orders of the Chief Commissioner, communicated to me in Mr. Ridsdale's letter No. 63 T., dated the 10th January 1879, to which I replied in my letter No. 133A., dated the 25th January 1879, that I hoped to be in a position to extend the Charduar plantation by one square mile annually in 1881-82 and thereafter. At the same time Mr. Ridsdale's letter quoted above was written, the Inspector-General of Forests visited Assam, and after close inspection of the Charduar plantation declared it a great success. His views on the subject have been recorded in paragraphs 91 to 104 of his report regarding forest administration in Assam. He suggested an annual extension of the Charduar rubber plantation by 200 acres, at an estimated cost of R36 per acre, or about the same as I estimate now the cost of future extensions.

15. Thus far I have given an account of the Charduar rubber plantation as an experimental undertaking only, and shown that it has been a perfect success as far as the growing of the trees is concerned; but it remains to be considered what the financial results of the undertaking are likely to be, since, as I have always held, and do now, the financial success of forest management is the only sound basis on which it can be permanently established and maintained. To make an even approximately correct estimate of the probable revenue that may be expected from these plantations, it is first and foremost necessary to know what a rubber tree will yield, and on this point our information is most imperfect. The statement made by rubber collectors are quite unreliable, and the exhausted state of the naturally grown rubber trees has prevented us until last year from making experiments; the result of last year's experimental tapping, as recorded in Appendix IX of last Annual Forest Report (1882-83), interesting as it is, and much as it has increased our knowledge of the yield of caoutchouc from *Ficus elastica*, still leaves us in considerable doubt on the subject, as has been stated in paragraph 118 of that report. However, so much is certain, that a full-grown rubber tree of about 50 years old will yield at the very lowest 5 seers of rubber, if very carefully tapped, and this quantity may be expected about sixteen times, which will be an equally safe estimate for calculating the yield of a rubber tree. To be quite on the safe side, I will only calculate 10 trees per acre, which would give us about 20 maunds of rubber from every acre. This, at the price at which rubber was collected last year in the Darrang district and sold, and deducting the expenditure incurred on collecting it, would give us a net profit of R54 per maund or R1,080 per acre in 50 years, and if the rubber trees have a longer life, the yield may be reckoned for their remaining years of life at the same, if not at a higher rate.

16. An acre of first-class timber trees would cost about double as much to plant and maintain, at the rate of 60 trees per acre; and taking the value of the trees at R10 each (the present royalty charged), this would give us R600 only, as compared with R1,080 from rubber, and most of the first-class timber trees will require 100 years to reach maturity, or double the time of a rubber tree. This means, in other words, especially if the compound interest on the capital used is taken into consideration, that an acre planted with rubber-trees will give about four times as much revenue as an acre planted with first-class timber trees.

17. It may be, and in fact has been, argued that rubber might be produced artificially, and that thus a fall in the price might be brought about. I think there is little to be feared in this respect, not more so than timber has to fear from the extended use of iron; and rubber, being a raw product, has a great advantage, inasmuch as the artificially produced article would have all the cost of manufacture added to the cost of the raw materials, and I myself have not the slightest fear in this respect. The price of rubber has been very high for many years now, and during this time it is known that efforts have been made to produce artificial rubber, but that they have failed.

18. It now only remains for me to consider the value of *Ficus elastica* as compared with other trees yielding rubber, both as regards quality and quantity, and although it must be admitted that the rubber yielded by our indigenous tree is slightly inferior to that from some other rubber trees, the difference is so little that in my opinion it has nothing to fear in this respect, and as to the quantity yielded by other species we have positively no authentic information to make comparison; but I am very doubtful whether any of them will yield more than *Ficus elastica*, and certainly the difference, if any, could not be so much as to make the cultivation of the latter unadvisable.

19. Of the two exotic rubber trees which have been tried in Assam, *viz. Hevea braziliensis*, the Pará rubber, and *Manihot glaziovii*, the Ceará rubber, the former has failed completely, as the climate of Assam is altogether too cold for it, and although the latter tree grows remarkably fast during the first year or two, and seems to thrive very well, its appearance is not at all such as to make me hope that it will do as well as our indigenous trees, much less that it will do better. Nothing positive can be said on this score until experiments with both have been made under careful supervision by a competent and responsible officer.

THE RED AND BLUE GUMS AND LEAF DISEASE.—A correspondent in New Zealand communicates to us a curious fact. It is, that, while the blue gum in that colony is as much liable to disease in the leaves as it is in Ceyloo, the red gum shows no appearance of disease. Our correspondent speaks of the red gum as growing with equal rapidity, but this is not the case. The popularity of the blue gum has been due to its free growth and its habit of having only one straight stem. The red gum is a slower grower, and it has an unfortunate habit of sending up forked stems. Damp sometimes lodges in the fork, and in high-winds the tree is apt to split. The tree itself is far handsomer in bark and foliage than the blue gum and the timber is much superior. The leaf-disease, which was so bad two years ago affecting the cinchonas, attacked also the red gums, but not with the same malignity as it attacked *E. globulus*. But of all the Australian trees it would seem that *Grevillea robusta* is the best to grow on Ceylon estates. Its timber is superior, being prized in Australia for tallow casks.

REPAIRING THE CLIMATE.

By telegraph from Melbourne we learn that the Agricultural Department intend to plant with trees 3000 acres in the You Yangs district, which has suffered much from drought since the original timber was destroyed. Baron von Mueller has reported as to the powers of the Eucalyptus trees to absorb water, and to condense into water the moisture contained in the air; he looks upon judicious planting as a help in maintaining and augmentiug water supply. Whether the Baron's theory is correct or not, the planting of these trees is a step in the direction which in this colony must be followed sooner or later. Nobody can doubt the absorbent powers of large flooded gums, as they are commonly called, and the power of trees as rain producers has been repeatedly discussed; but it is unfortunate that, while one set of theorists announce their belief that forests do with certainty increase the rainfall, there are others who tell us they can find no proof, in the experiments they have tried, that this effect will follow the re-planting of forests in country that has been denuded of timber, nor can they say with certainty that the rainfall decreases when natural forests are destroyed. Speaking unscientifically, the experience of Australia of late gives little support to the Baron's theory, for plains and forests have been equally subject to the want of rain; and there have been some strips of country where showers have fallen often enough to prevent loss of stock which appear exactly similar in the matter of vegetation to the dry strips beside them. The eucalyptus is a great absorber of water, and on that account is invalnable for planting where the land is marshy; and it gives off its moisture into the air also, but when this is carried straight off by wind into the parched interior it can be of little local use as an augmenter of the supply. Had we a high mountain range against which the clouds would be compressed by the wind, rain would be more certain; but the luxuriant growth of trees is only a proof that they receive sufficient moisture, not that they produce it.—*Queenslander.*

WINTER IN THE TROPICS.

It seems to be hardly realised how wintry is the aspect of the dry season in the Tropics. Many more of the trees in Africa are deciduous than we often imagine in our conjured-up mental visions of a fair tropic land, where perpetual verdure reigns, and the vegetation is a vague, indefinite mixture of limp Palms, with fronds like ostrich feathers, and rampant Bananas raising their florid greenery above the masses of formless creepers; but, nevertheless, when about a month has elapsed after the last rains are over, the aspect of an African hillside has much of the cheerless desolation of winter about it. The once imposing Baobabs, whose masses of verdure were fair to see, are reduced to mazes of leafless twigs; the ground is covered with a brown carpet of fallen leaves; many trees, though retaining their foliage, put forth no fresh shoots, and are yellow and seared with the hot sun; here and there an evergreen stands out, like an English Yew or Holly, in almost heartless contrast of dark cold green, amid its faded withered fellows, and next to it, perhaps, is a white skeleton of what was a short time since a tufted tree. The tall herbs, erewhile gay with gorgeous flowers, show now nothing but yellow stalks and shrivelled seed-vessels, in which perhaps there still lurks a point of colour in the red or orange seeds that gleam from under the brown husk. The many tiny flowerets, the mosses and fungi, are scarce to find; only certain repulsive plants—things with fleshy, mutilated limbs, weirdly swollen, distorted, and covered malicious prickles stand forth in disagreeable prominence, screened from view no longer by the fair and delicate creeping Ferns and clambering Lycopodiums, and seeming to stand unchanged and prosperous when all else fades and dies. In the great meadows through which th path meanders the waving grasses are laid low, and in their place are dismal tracts of black ashes where the bush fires have just swept by. But the dry season is hardly death so much as recuperation. It is a short pause—a sleep in which the expended forces of Nature are once more gathered in. Just as the earth in its summer solstice spins out from the sun's control like a restless child, and then, wearied with its wilfulness, lets itself be slowly drawn in again to run its sober winter journey, so its tiny children, who have rioted in all the exuberant excesses of spring and summer, need the repose of the slack months to restore their energies.—"The River Congo," by H. H. Johnston, F.Z.S.—*Gardeners' Chronicle.*

CHINESE VEGETABLE PRODUCTS.

In a report of a journey through the provinces of Tsuch'uan, Yünnan, and Kwi-chou, from Feb. 11 to June 14, 1883, some interesting notes occur on the vegetable products of the country traversed. At one part of the journey brick tea is described as being "made up into packets of 18 catties in weight. The tea is first enclosed in what looks like dried Banana leaf, and then cased with coarse matting. The packets are long and flat, and are piled one above another on a wooden framework extending above the carrier's head. At the bottom are usually a couple of half packets, which afford a good rest for the pole which the carrier places under his load when he wants a rest. The maximum load I have hitherto noticed was ten whole packets and two half packets weighing 198 catties—a good load to have on one's back for fifteen days—the time usually taken by these carriers between Ya-chou and Ta-chien-lu. The ordinary load was eight and nine packets. The freight between these two places is 300 cash a packet, so that if the journey is performed in fifteen days the wages of a carrier of ten packets amount to 200 cash a day. Among carriers of such heavy weights one would expect to find men of remarkable *physique*, but they seemed to be distinguished for 'want of leg.' The same applies to the salt-carriers. They travel slowly, resting every few yards and giving vent to their feelings, which on such a day must have been anything but amiable, in a low whistle, or rather half-whistle and sigh. The brick tea manufactured at Ya-chou for the Tibetan market is altogether different from the brick tea manufactured by foreign merchants at Hankow. The former is entire leaf and twig loosely pressed, while the latter is tea dust firmly compressed into actual brick-shape." "Beyond Tung-ching Hsien the valley contracts, and the hills on either side become more precipitous, rocky, and uncultivated; frequently the bed of the stream occupies the whole valley, while the road runs along the hillside. Some distance south of the city the hills are thickly dotted with the Tea shrub growing on very rocky ground, and we met a number of carriers with bundles of brown leaves and twigs, which we took for dead leaves collected for firewood, but which turned out to be 'tach'a,' great or coarse Tea. It was bound for Ya-chou, and will doubtless find its way back along the same road to Tibet." At another point of the journey the Mulberry, Orange, red Date, and Pear trees were frequently met with; the Orange is described as a tall tree with a small fruit with a thick and wrinkled skin, so thick indeed that the edible portion of the Orange is reduced to a minimum. A very remarkable fibre, about which something more will, it is hoped, be soon found out, is described in the following paragraph:—"At Hai-t'ang I procured a specimen of a coarse cloth, manufactured from the fibrous root of a grass which grows in the gullies of the mountains in the neighbourhood. It is called the 'fire cleansing cloth,' and is used for dusting and other purposes. The peculiarity of the cloth is that when it is dirty it is put in the fire, the dirt is consumed, and the cloth is taken out clean and uninjured and ready for use. I can vouch for the truth of this, having made the experiment myself." The white wax insect is said to be the chief produce of Chien-chang. Little white wax, however, is produced as compared with other producing districts, such as Chia-ting Fu, which depend entirely on the Chien-chang valley for their supply of insects, and it has hitherto been matter of surprise that the valley of Chien-chang should produce the insects and not the wax, and Chia-ting the wax and not the insects. The reason is perfectly simple, however. In the Prefecture of Chia-ting the Wax tree is extensively grown; in the Valley of Chien-Chang it is not. The white wax insect does not grow on the Wax tree, but on the Tung-ching tree which is widely grown in the Chien-chang valley. A small twig of this tree, the scientific name of which does not occur, is described as containing about half-a-dozen round excrescences about the size of a Pea, and innumerable smaller excrescences like minute shell-fish clinging to the bark. On opening one of the brown glazed Pea-shaped excrescences

thousands of minute whity brown creatures, whose movements are all but imperceptible to the naked eye, are seen. In less than a mooth's time the excrescences would be collected, transported, and suspended on the branches of the Wax tree. At first they spread themselves on the upper side of the leaves during the night, but hide during the day from the sun under the leaves. After a time they spread over the branches and secrete the wax.

The narrative from which the foregoing information is gathered is worth the time occupied in its perusal. It is printed by Harrison & Sons.—*Gardeners' Chronicle.*

THE PRESENT ASPECT OF THE SUGAR INDUSTRY IN QUEENSLAND.

There is a very marked difference between the aspect of the sugar industry now and what it was only a few months ago. The most casual observer cannot fail to perceive this, nor is it difficult to arrive at the exact reasons for it. On every plantation visited by our agricultural reporter the same ideas were found to prevail, and the same anxiety to reduce operations to as small dimensions as possible was manifest; and this on account of the uncertainty regarding the labour question. Enterprise and capital are staggered at the present outlook. Very large sums of money have been invested in an industry of an exceptional character, an industry the success of which mainly depends upon exceptional circumtances, and an industry which has already furnished a history fluctuating and uncertain, at present a very fair success, but formerly franght with many disappointments and heavy losses. Although sugar-growing has come to be fairly successful, clearly that success is owing to the high prices ruling for the manufactured product in the local markets, the low price and plentiful supply of reliable labour, and the facility with which a sufficient area of good land for the purpose could be acquired. Under these circumstances rapid growth of the industry and immensely increased production of sugar naturally resulted; and now a somewhat serious reaction has set in, consequent upon changes in all these particulars which have so far fostered its growth. A short time since the average value of a ton of sugar was fairly estimated at £20 or even £25; now, however, it has dropped to from £15 to £17. Kanaka labour formerly cost the importer from £10 to £12 per head, and now it is reckoned at £25. A few years ago land for sugar-growing could be selected in any quantity at a nominal yearly rental, said rent forming the purchase money of the estate; but now if land is wanted of certain quality, with the necessary facilities for for working the industry to proper advantage, it is valued so highly by the present owners that to acquire a freehold of sufficient extent necessitates the disbursement of a large sum of money, the fair interest on which is something considerable. Under these changed aspects, therefore, it is by no means surprising that capital is not forthcoming for the extension of the industry, and that the banks have closed their coffers against would-be borrowers on such property.

It is strange that so rapid a change should have taken place in a business which only a few short months ago was so full of promise; but the fact confronts the observer at the present time who moves among those interested in any way in the sugar industry in the North; for it is a topic almost always on the surface and works its own convictions in every way and through the medium of every sense. Sugaropolis—as Mackay is so frequently called—is at the present time the embodiment of dulness and depression. The town wears the appearance of having outgrown requirements, and of being very much overdone; but a careful inspection of the immense industry which surrounds it on every hand, and which proved the lever to move it into its present advanced stage of growth, is ample to warrant all that the town can show. But although history thus read appears strange it is not inexplicable. Queensland sugar-growers are coming more and more into competition with those of the same craft elsewhere, who have in every way the advantage of them, and will naturally fight hard to maintain it. This is telling upon the value of the manufactured article in the first place, and the unsettled state of the labour market is indirectly playing into our rivals' hands.

The pressing difficulty, and that which most seriously affects the industry, is the present aspect of the labour question. The fact that a sufficient supply of suitable labour is not, under existing circumstances, obtainable is having a most depressing effect upon all engaged in the industry. It is crushing all the bright hopes that were so recently entertained as to the future of Northern Queensland, and it is destroying the enterprise which has up to the present time been displayed in developing our northern agricultural lands. Tidings reach us from time to time from various sources of a determination in all the principal sugar centres, not only to stay the extension of the industry but to reduce it within narrower limits. The South Sea Island labour now available is in many ways unsatisfactory. It is anything but cheap: the boys cost per head to introduce £25, and the expense of housing, feeding, and overseeing them is estimated to average little if anything short of £1 per week each. In many instances the recruits are mere boys, and unsuited for doing a man's work; in many others they are diseased and have to lie by a good deal of their time and receive medical attention and nursing; and frequently, with all the care possible, they die wholesale on the planter's hands, thus incurring a heavy loss to the employer. Kanaka labour, it will thus be seen, is not cheap labour; its only redeeming quality is its reliability. No other labour as yet tried is nearly so reliable. The "boys" work cheerfully and well under European oversight; anything they may be put to is all the same to them; and when the stress of labour comes upon them they serve their masters without worrying them by perpetual strikes and foolish agitation. This labour has not been prohibited, but it is not adequate for the purpose, and, moreover, it has been put under restraints which will in operation prove inimical to the interests of the kanakas themselves. In every batch of boys which go on to any plantation there are weakly ones who are unfitted for ordinary field work. It haa been the practice to set these apart for pottering jobs about the house and the like, where there health and consequent services could be the better secured; but now that this is made illegal they must go into the field, and very likely die under the hardships to which the changed laws of the colouy expose them. Then, again, the "boys" available now are proving iuferior to former importations and in every way are disappointing the expectations of the planters. No one at all familiar with plantation work and requirements will for a moment entertain the thought that European labour will ever serve for the purpose. Its cost will not debar it, but its unreliable character will effectually close the purses of capitalists; and, besides, the day is very distant when European labourers will contentedly settle down to field work ou the plantations of tropical Queensland. When they do so they will be the slaves of circumstances which they can neither resist nor control, and such a prospect we may safely say is not immediate nor in any sense desirable. All those interested in augar growing, as well as those who, from observation, are qualified to form an opinion on the subject, think that the only satisfactory solution of the present difficulties lies in the introduction of coolies under proper reatriction. Tamil coolies can be had in any quantity, and of certain quality, from a uear portion of the British dominions, and they seem to be the very thing to answer every purpose. If this is the only efficient remedy for the failing of the great sugar industry, what reasonable objection can be urged against carrying it out? This is the question occupying many thoughtful minds at the present time in the sugar centres of the North; and it is a question which concerns people of all classes in the South very closely, as they will discover when too late should the sugar indutry be allowed to collapse.—*Queenslander.*

FARM MEMORANDA.

(From the *Leader.*)

PROFESSOR STEWART celebrates the cow as "the most remarkable producer among animals." She gives at her best seven times her own weight per annum in milk; of food value twice as great as the beef creature of equal size gains during the same time.

TO BREAK up sitting hens do not drench them in water nor put them in a barrel with an inch or two of water in the bottom, nor tie them up by one leg to a tree, nor any of these cruel practices; but take them from the nest, but them in a large coop in the open air, under a shade tree if the weather is warm, and feed them largely with everything, including baked bones, that you give to your laying hens. In many cases the fowl commences to sit

when she is in good condition to keep on laying eggs if we can but get the notion out of her head that she must be a clucking mother. She needs, perhaps, the material for egg shells, which may be easily supplied. Furthermore, she should not be put in a small crop where she will sit down and not obtain exercise; better put her in a pen having no floor but loose earth, where she may scratch for a living. Activity will tend to forgetfulness of the sitting fever, or desire to sit. It is not a bad plan to put a cockerel in with her in the pen.—*San Francisco Chronicle.*

THE SUB-IRRIGATION SYSTEM.—This system has attracted considerable attention of late on the part of skilful and scientific agriculturists, and it is interesting to know that some trials have been made in America which have fully established the great value of the process. Mr. Biggs, a prominent horticulturist in California, has tried the plan in an orchard of 150 acres in Solano county, and he found that the product was so increased in quantity and quality as to pay the cost of the improvement in one year. Mr. E. W. Steele, also a leading agriculturist in California, has also introduced the system on his land. Trenches about 18 inches in depth are dug at intervals of 7 feet, and as long as required to cross the piece of land to be irrigated, and in these a cement pipe 4 inches in diameter and of 2 inches open bore is laid by a machine carried along by hand, making the pipe continuous, like a gigantic sausage. While the cement is still soft, holes are punctured in the pipe at intervals of 7 feet, and in each of these a perforated plug is inserted, through which the water, when let into the pipes, will percolate and irrigate the ground. To prevent the plugs from being stopped by the overlying soil, a cement cap is placed over each in such a manner that the water may always flow freely. These pipes connect with a main trunk of 4 inches or 6 inches in diameter, through which the supply of water runs. The pipe of various sizes is made on the place at a small cost, and when dry and set becomes as hard as a stone and strong enough to hold a column of water of 50 feet pressure. Large cisterns, distributing boxes and drain and sewer pipes have been made of the same and act excellently. This system of sub-irrigation has proved most successful in every way.—*Alta California.*

STALE BREAD.—A great deal of bread is thrown away by those who can ill afford it from the lack of knowledge how to utilise it. On the farm, in most instances, of course, stale bread is not wholly lost, for if wet a little it makes good food for the poultry, or may be given to the pigs; but this is not the best way to make use of it, even by those who have poultry and pigs. There are many ways to utilise stale bread. It makes delicious griddle cakes when soaked soft in cold water. Three small slices with water enough to cover them should be sufficient, when the milk and flour are added, to make about two quarts of batter. Some prefer to put in one egg, while others like them fully as well without. When the bread is soaked soft make it fine with a spoon, add the milk and sufficient flour to stiffen enough so that the cakes can be easily turned. If sour milk is used, add to the batter one even teaspoonful of cream of tartar dissolved in a little water, and an even teaspoonful of soda. If you do not use sour milk use twice as much cream of tartar as soda. French toast, always a favorite dish with children, can be made of thin slices cut from a stale loaf and moistened in milk and eggs—two eggs to a pint of milk—and then fried on a griddle with a mixture of butter and lard, or butter and beef dripping, and may be eaten with sugar or syrup, like griddle cakes. Pieces of bread which are not too hard can be made into a resemblance of turkey dressing. Cut the bread into dice, and if you have a quantity of gravy from which fat can be taken, left from any kind of roast (though a piece of butter will do as well, thoroughly grease the bottom of a spider, put in the bread, with some little chunks of butter and plenty of seasoning; then pour enough boiling water on to moisten it, cover tightly, and in a moment it will steam through, and you can stir it, and either brown a little or have it moist like dressing. It should be eaten with gravy over it, and is a good substitute for potatoes. The little dry hard pieces and crusts which always accumulate can be put on a pie-tin in an oven that is just hot enough to dry and make them a light brown, and then roll them fine and put away to use in making croquettes, frying fish, &c. Even these slightly browned crumbs make excellent griddle cakes with the addition of one egg and a handful of flour and milk to make a batter. Stale bread may be utilised in making a custard pudding also. The fact is that where economy is the rule bread will not be thrown away.—*San Francisco Chronicle.*

PRESERVING POTATOES.—Ure's *Dictionary of Arts*, 1878, Edwards's system:—"The potatoes are cleaned from dirt, and then boiled or steamed until their skins begin to crack. They are then stripped of their skins, the eyes and specks carefully picked out, and are placed in an iron cylinder. The cylinder is tinned on the inside and perforated with a number of holes, one-eighth of an inch in diameter, through which the potatoes are forced by the descent of a piston. The potato pulp is then dried, by spreading it thinly upon hollow iron tables, which are heated by steam to from 100 deg. to 160 deg. Fahr. During the operation of drying the pulp is well raked, and afterwards it is packed in casks. The steam is supplied from a boiler, in which it is kept at a pressure of 10 lb. to the inch, and the heat of the cables is varied by opening and closing the cocks upon the supply pipe, the heat being lowered as the potatoes approach dryness." John Mockart's mode of drying is thus described:—"The potatoes are well washed, and the peel or outer skin is then removed by means of any suitable apparatus, but in preference employing a rasping or roughened surface drum, revolving at a high velocity, fitted into a wooden case and closed in, so that only a long narrow opening is left at the top or side of it. In this opening a stream of water is caused to flow, and the roots to be peeled place therein. The eyes, if not taken out by this apparatus, are picked out after they are taken away from the revolving drum. The potatoes are cooked, squeezed through the perforated plates on to drying beds or trays, heated by steam. When the mass is thoroughly dried it is ready to be packed for storage or the market in convenient receptacles." By Elijah Slack's patent the potatoes are primarily submitted to the action of acids and alkalis, as well as to that of diastase in solution, and other saccharine matters. The treatment is said to be a powerful preservative action, arresting disease, and enabling the owner to keep the potatoes for a lengthened period, the routine of operations being varied if necessary. Mr. Pulleine, of Adelaide, claims to use a new process, which is said to be cheaper and equally as good as the older ones.

THE "CHICK" HOUSE OR INDIAN CONSERVATORY.

In 1871 I went to the Royal Botanic Garden near Calcutta. I saw there that the then Curator, Mr. Scott, had been successful in growing Orchids and Ferns under a grass roof, such as is used by natives for growing the "Pan-vine"—a species of Piper (see *Gardeners' Chronicle*, p. 281, vol. xix.).

On returning to Lucknow I conceived the idea of trying a modification of what I saw in Calcutta, suited to a climate where a hot dry wind usually raged between March 15 and June 15, sometimes even later. In the Horticultural Garden I erected a house covered on all sides and top with "chicks" of reeds, called "Sentha," that is, the dry stems of the Saccharum moonja. A "chick" is a blind made either of these reeds or of strips of Bamboo, more or less thin, and fitted to doors and windows of Indian bungalows.

During the process of erecting this house I made some interesting experiments. I supported one of these blinds horizontally across some Bamboos in sunlight; then I took a sheet of paper and held it close to and parallel to the reeds. I found that the direct sunlight passed through and alternated with the shadows of the reeds. By moving the paper from the reeds I found that their shadows broadened, and eventually crossed each other, producing a light totally different from direct sunlight, and resembling at a certain distance a sort of moonlight. Thinking over the matter I came to the following conclusion:—As the sun's disc at its distance from the earth is broader than the reeds, it follows that close to the reeds there will be alternate sunlight and dark shadows, but that at a certain distance the shadows and lights would mingle and produce a subdued light, such as, for instance, would be produced under a tree by the mingling of the shadows of the leaves and the sun's rays that pass between them. The same

thing may be illustrated by making a pin-hole in a door and allowing the direct rays of the sun coming through it to be received on a sheet of paper behind the pin-hole. By moving the paper from the door it will be seen that the picture of the pin-hole enlarges in diameter as it recedes from the hole. The reason, of course, is that the disc of the sun being larger than the hole the rays proceeding from the edges of the disc cross each other at the hole and diverge again *ad infinitum*. The difference of size between the sun's disc and the diameter of the reeds is, I take it, the reason of the beautiful subdued light which fills the interior of the "chick" house—so suited to all plants which, in a state of Nature, are found in forests, and lighted only by the mingled lights and shadows produced by the leaves and branches of the forest trees and bushes. Before setting up my first "chick" house in the Lucknow Horticultural Garden many plants, including Ferns, could not be grown at all. By irrigating the soil under this house from a well, a moist ground and atmosphere were kept up in the driest season. The screen of "chicks" protected the plants not only from the scorching hot wind outside in summer, but to a great extent from the frost in winter. In my annual report to Government of 1874 I find the following:—

"The most successful experiment of the past year has been the 'chick' house or conservatory. It has answered for many things beyond my most sanguine expectations. Pteris longifolia and cretica, Asplenium esculentum and dentatum, Nephrolepis exaltata and tuberosa, Nephrodium molle and truncatum, Polypodium proliferum, lineatum, and irioides; Cheilanthes formosa, Adiantum Capillus-Veneris and caudatum—all Ferns—thrive with a luxuriance which cannot be surpassed in their native habitats. The Acalypha tricolor, which delights in the moist, hot climate of Bombay, lit up the conservatory with its painted leaves. The superb Helicenia (now, I believe, called Musa coccinea), resembling a dwarf Plantain, flowered under this cover for the first time, and produced a head of brilliant scarlet bracts. The wiry Passiflora kermesina climbed up the posts with great luxuriance, and festooned itself between them, dropping here and there its graceful branches, studded with crimson starlike flowers. The exquisite Selaginella lævigata, with its creeping stems and lace-like fronds; the Eucharis amazonica, with its waxy milk-like flowers; the large-leaved Scindapsus, exotic Palms, and Araucarias, with their varied and charming foliage—all these and many other delicate plants have found a home in this conservatory, and promise to become a great acquisition to Lucknow. This house is 64 feet long, 40 feet wide, and 8 feet high."

A judge in the Indian Civil Service, who came out with me on my return from furlough in 1881, told me one day:—"Your 'chick' house made quite an era. We had a very nice one put up in our compound, and used to have *chota hazri* (early breakfast) in it every morning, surrounded by Ferns and other pretty things."

Of course such houses can be made more expensive and permanent with iron posts and framework. Later on, indeed, a very fine conservatory of this kind was erected in the Royal Botanic Garden at Calcutta. There, however, it was covered over with wire netting, and over this were tied leaves of a long kind of grass. Many other "chick" houses were erected in different places. I made a tour in South India last year. At Bangalore and Madras I saw them—although there, instead of "chicks" they use open mat-work made of thin laths of Bamboo, with meshes about an inch or so wide.

These "chick" houses are invaluable for hot climates, where the frost in winter is insignificant. They temper the heat and dryness of the atmosphere to a remarkable extent. In the rains, the atmosphere inside is apt to become too damp from want of ventilation. To counteract this, I made windows all round, closed with "chick" blinds during the hot and winter months, and opened up during the rains.

It is interesting to find that the "lath shadings" in use in France, and now being introduced into England, answer the same purpose, in mitigating the force of the direct sun-rays, and the subdued light produced under them is explainable by the same causes as stated before. The screen of whatever material made, must be a certain distance from the plants, so that the sun-light may reach them after the shadows of the laths have crossed, in order to exclude direct rays. If the plants are placed immediately below the screen, they will, I have no doubt, still be scorched where the direct rays touch them.

It would be interesting to know at what date the French began to use these lath shadings, in order to ascertain whether they took the hint from our "chick" houses. In Florence, in 1880, in one of the nursery gardens, I saw a structure something similar to our "chick" house for summer use.

These houses can be modified in various ways. One I roofed with dried leaves of the common Phœnix Palm; another I roofed with "chicks," leaving the sides all round quite open. Being screened on the wind side by trees, the latter made an admirable place for germinating seeds of all sorts in pots and for raising young plants.

I believe that houses covered in this way might be used in England during the summer for screening plants from the sun and wind. In a country where everything is made by machinery something might be devised of a permanent nature—such as wire screens—like "chicks" and painted; or screens made of strips of zinc. Both these might, however, radiate too much heat towards the plants. The "chicks" or blinds that are now made in England for windows, of thin strips of wood would, I think hardly answer, as they are too close, and would not stand wear and tear. In Florence I saw blinds of this kind made of a strong wiry reed called "Giunco." These would promise to be more durable, if the string which binds them were tanned or tarred.—E. BONAVIA, M.D., Etawah. [Such houses are, we believe, common in Italy—we have seen them in the Pisa Botanic Garden.—ED.]—*Gardeners' Chronicle.*

PEATY SOILS AND THEIR TREATMENT.

Peat consists of an accumulation of vegetable matter, in a state of greater or less decomposition. It is generally found in low, moist situations, where mosses, lichens and other plants grow, which are with difficulty decomposed; these become interwoven, and unite with the mud and various substances deposited by the water; the whole amalgamates, vegetables putrefy, and gradually lose their organic texture, and are at length united with the other substances into a compact spongy mass.

There is this obvious difference in the origin of peat soils, and those of sand, chalk, gravel, clay, &c.; the latter have been formed by the geological operations of nature, and generally brought from a distance, and deposited by the action of water; but peat soils have been formed wherever they now exist. A soil covered with peat is a soil covered not only with fuel, but also with manure. It is the excess of manure only which is detrimental; and it is much more easy to destroy than to create it. To cultivate a bog is a much less difficult task than to improve a sand. If there is a proper level to admit of draining, the larger the scale of operation, the less the comparative expense must be, because machinery for many purpose takes the place of manual labor.

As peat is formed by the decay of various kinds of plants, so it will be found to differ in its qualities. Nothing so clearly indicates the quality of peat as the plants which it spontaneously produces, for the moss soil and its products are nearly the same substance, and the crop of the preceding year is the soil in which the next year's crop vegetates. Again, the moss plants now vegetating indicate the degree of moisture; for, as soon as a permanent saturation is effected, the sphagnum, &c., is produced, to the almost total exclusion of the other plants; but, on the water being drawn off, it dies, and is succeeded by heath and sundry coarse aquatic grasses; or, if rendered sufficiently dry, bent grass prevails. If decomposition is by any means effected, then rushes, and also the finer pasture grasses, supplant the latter. While moss plants continue to grow, it is evident that the depth of the moss must be still on the increase, and this by means of the antiseptic qualities of its products; but where, by any means, pasture grasses, or even rushes abound, it is manifest that the proper moss is in a state of decay; decomposition has commenced, and a very different treatment is called for. Peat soils include a large proportion of several counties of Great Britain and Ireland. In the Falkland Islands almost every kind of plant, even the coarse grass which covers the whole of the

surface of the islands, becomes converted into this substance. In the Terra del Fuego, nearly every patch of ground is covered by two species of plants, which, by their joint decay, compose a thick bed of elastic peat.

How may peaty soils be improved?—The first step of improvement is to acquire command of the water, and obtain an outfall, by digging a ditch, which will take the place of the winding stagnant rivulet frequently found in bogs. A system of draining must then be pursued, adapted to the extent of the ground, and the levels that can be obtained. The draining completed, paring and burning should be followed. When the dry easterly winds of spring set in, the breast ploughs should be put to work, the surface pared and turnd over, and, when dry, piled in heaps and burned to ashes.

Rape, or seeds being established as the first crop after the breaking up, the next crop is usually oats. They are drilled in upon a very shallow furrow, with plenty of seed, and well pressed with a press roll, as well before they have come up as afterwards, in order to guard against the wire worm, the enemy to be feared on such land. This first crop of oats is generally beaten down by the weather, being weak and long in the straw; and though not a bad crop, looks better than it really is. On land which is not peat, but peaty, some farmers grow barley. There is a large crop of straw, and it is therefore liable to be laid; the grain, too, is thin. The advocates of barley, however, assert that a bad sample of barley is better than a bad one of oats, because thin barley may be ground, or may be used for seed, whereas seed oats should be as plump as can be found. The oats or barley are followed by rye grass, which has been sown among then; but if these have been laid, as they often are, large patches of the rye grass will soon be destroyed.

When wheat is sown on ground that is at all peaty, it will almost certainly lose plant in large patches, even though the land has been dunged, and the young wheat has been trodden in by women, as is sometimes done. This is because there is some principle defective in the soil; that principle is cohesion, and can only be supplied by clay. The fen farmers of Lincolnshire, accordingly, apply clay to peat land, by a process which has been carried on for many years. Mr. Cuthbert Johnson disapproves of the practice of paring and burning, being of opinion that it merely furnishes the soil, by an expensively rapid process, with the freed earths of the peat, which its gradual decomposition would, by other modes, more profitably and steadily effect. He recommends the breaking up as deeply as possible, by the common and the subsoil ploughs, the surface of the peat; and then, if good well burnt lime can be procured, there is no earthy addition so rapid and so powerful in dissolving and rendering pliable the peat as this. A few ploughings, assisting the combined operations of the atmosphere and the lime, will in a few weeks bring the soil into such a state as to enable it to bear a first crop. The quantity of the lime should be about 250 or 300 bushels per acre; but the quantity, of necessity, must vary with the readiness with which the lime is procurable. Where it is very expensive, the cultivator is obliged either to reduce the quantity, or mix it thoroughly with a proportion of clay or marl, before he spreads it over the surface of the peat. Where limestone is to be obtained in the immediate neighbourhood, and other fuel is not to be readily procured, peat may be employed in many cases in the process of lime burning without much difficulty, it chiefly requiring that the peat should be thoroughly dried previous to its being used.

For a first crop on the thus reclaimed peat soils, I have found no other crop equal to potatoes. These are best planted in ridges; the horse hoe plough can then be easily kept at work, which not only considerably promotes the decomposition of the peat by facilitating the introduction of the moisture and gases of the atmosphere; but this operation adds very materially to the vigor and produce of this valuable root, than which no plant more delights in fresh soils, such as that produced by well drained fresh earth dressed peaty lands. It is well to avoid for a year or two all attempts to produce corn crops on land like that now described. The course of cropping which the farmer will almost always find the most profitable is to follow the potatoes with peas, then turnips, oats, grass seeds, peas, wheat. In all cases, too, he must remember in what small proportions some of the essential ingredients of his crops are at first existing in this peaty soil, and how valuable even a slight dressing of clay or marl will be found in supplying such deficiencies.

Example of Improvement.—The fens of Lincolnshire have been increased in productiveness at least 100 per cent. merely by applying to the surface of the peat the clay which is found at depths varying from 2 to 5 feet below it. This application is made thus:—Trenches, parallel to one another, are made 11 yards apart and 3 feet wide, down to the clay; and then 2 feet in depth of the clay is thrown out, one-half on each side. The effect of this, after the second year, is greatly to increase the productiveness of the soil—in many cases to double it. This mode of improving peaty soils extends over a large district; indeed it is equal in extent to the extent of the fens, for, although the whole of the fen land in Lincolnshire, Northamptonshire, Huntingdonshire and Cambridgeside has not been so treated, yet there is scarcely a farmer but has begun and is now proceeding with this improvement.—*Gardener's and Farmer's Reason Why.*

ON COTTONSEED AS FEED.

Prof. John A. Meyers, of the Mississippi Agricultural College, delivered an address, not long since, on cottonseed as a feed for stock. He said:—

In this age of science we must run our engines, raise our crops, produce our stock, cultivate our soil and acquire our wealth under high pressure. The man who can send his products into the market first, obtains the highest price. The people demand juicy, tender fat, young beef. In order to produce this class of meat, scientific cattle feeders have carefully studied the best means of feeding stock so as to attain the desired end. Looking at a feedstuff as chemical body he considers it, so far as his objects are concerned, as composed of four constituents, viz., protcine or albuminous matter, carbohydrates, fats and mineral matter. Of the latter we have nothing to say, but the first three play an important part in determining the character of the rations. Proteine matter goes chiefly to the building up of the muscular tissue of the body. The carbohydrates and a portion of the fats are oxydized to produce the necessary warmth for the animal system, and the remainder of the fat is probably utilised in building up the fatty matters of the body. By nutritive ratio we mean that the percentage of proteine matter present in food bears to the sum of the carbohydrates and fat as shown by chemical analysis. It is an important element to take into consideration in the preparation of a ration.

The giving of a large quantity of food to an animal or the using of a badly balaneed food does not accomplish as much as a smaller quantity, all of which is relished and digested. For every 1,000 pounds of live weight, from twenty-four to twenty-six pounds of dry matter is all that cattle or horses will digest, and should have, approximatingly, the nutritive ratio of 1·5. The fats may have ratio to the albuminoids of from 1·1 to 1·3, and should vary with the age of the animal and the object to be attained. In preparing the rations for an animal we take as our standard milk and the very best hay.

By experiment we find methods of using a large amount of material for food which could not otherwise be utilized. We may also devise rations which will be especially suited to the animal when being worked or while at rest, or when being fattened for slaughter. In the preparation of these rations we are not very particular what we use as feed stuff, just so we get the proper amount of digestable ingredients into the rations, and do not have a flavor present that will cause the animal to reject the food. The preparation of food according to scientific principles, should have in view the using of such materials as are within reach; the feeding of the animal with as little expense as possible; the preservation of the animal in good health, and the stimulation of its digestive organs, so as to cause it to develop rapidly in order to be ready for the market as soon as possible. In order to secure a food having all of the properties it is necessary very often that the food should be well ground or cut, and in some cases cooked or steamed.

As chemists, to within reasonable limits, we understand the office to be performed by the food taken into the

body, and have determined the relations the different constituents of the food bear to each other and to the animal body. We find that the animal must appropriate from the vegetables all of the substances of the muscles and fat, and probably has no power to combine them from their elements so as to form the required compounds. The fibrine of the blood is the same as that of the wheat. The albumen of the egg and of the vegetable are the same. Casein of milk and the lagumen of the bean are similar. In the language of another: "These substances are all convertible into each other in the animal organism." If this is true, the food of animals should be compounded in regard to the result desired. A certain quantity of food will sustain the animal in health. It must be modified if we desire to fatten or work the animal. The necessary variation is very small, it is true, but in it is shown the skill of the scientific feeder, and it is often sufficient to obtain the result sought. We do not have sufficiently accurate information concerning the feed value or nutritive ratio of many of the feed stuffs of the South to give you perfectly accurate formulas for the economic use of many of these feed stuffs. So far as I am aware no attempts have been made to construct formulas for the rations for stock using Southern feed-stuffs entirely. We have formulas using some of the Southern products, which are largely and profitably used in the Eastern States, England and Germany. In presenting you with a few formulas, in all of which cotton seed meal is used instead of corn or oats, we acknowledge that it is more than an attempt at introducing the principles of scientific feeding into the South. Similar formulæ cannot be at present constructed for all of our feed-stuffs, as our government has not yet seen fit to direct much of its attention to the development of the knowledge of the Southern feed-stuffs, and the enterprise of a few chemists of limited resources is inadequate to the task. We trust, however, that farmers and those interested in the cotton seed mills will find them of some service.

Here follows a long and rather complicated table which we cannot give in full for want of space. The main showing of the table is that cotton seed meal is richer in "albuminoids" than any other stock feed now in general use. It is also very rich in many of the other principles necessary to the making up of an entirely first-class feed. We quote further:—

There is not an animal produced upon a Southern plantation that cannot be fed and fattened upon the productions of that plantation if they be properly prepared. It is simply the nonsense of fashion which leads the Southern farmer to send to the Northwest for his feed. The Mississippi farmer has at his door 550,000 tons of the very best feed-stuff in the world, worth at the rates, at which we calculate the food values of different materials, $22,880,000. If we compare this with the oats crop of Illinois, which produces more than any other State, we find that crop worth only $25,558,000. We pay high prices for grain brought from the North, while we ship away or allow to waste a better feed-stuff, obtaining for it less than half of its value.

The farmer of the North can well afford to ship grain here and buy back cotton seed meal. The values stand as follows:—If corn is worth per 100 pounds $1.11 as a feed stuff, cotton seed is worth $2.08, cotton seed meal, $2.30; oats, 98 cents; cow peas, $1.33; good hay, 75 cents. These valuations are given in "Stewart's Feeding Animals," which has lately been published and are based upon the most carefully made analyses.

The feed value of the cotton seed meal and cake are not appreciated by the Southern farmers as they are by those elsewhere. Where competition is the greatest and the farmers the most intelligent, or where there is necessity of economic feeding, we find cotton seed is most highly prized. There we have no complaints about its killing stock. It is only where the farmers are so careless as to allow their stock to eat too much of it without other food that it will kill the stock. Corn, wheat and oats, under the same considerations, would do the same, probably, though, as they are not so rich they are not so likely to do it as the rich cotton seed and its products are. We have no hesitation in saying that the cotton seed meal or cake is one of the best feed stuffs that is produced in any climate. The meal is better than the seed. * * *

The chief interest that we have in the cotton seed is centered in the kernel, which constitutes just about one-half of the seed by weight. If we look at it as a feed stuff it is composed of fat 36·55 per cent, nitrogenous matter 29·25 per cent, carbo-hydrates 19·52 per cent, crude fiber 4·38 per cent, according to Dr. Dabney, giving a nutritive ratio of 12·07.

If we take the seed as a whole, it has: Ash, 7·8 per cent, albuminoids 22·8 per cent, of fiber, 16·0 per cent, other carbodydcate 15·4 per cent, fats 30·3 per cent—nutritive ratio 4·6, according to Wolf.

The ash is composed, according to Wolf, of potash 32·15 per cent, soda 8·75 per cent; lime 5·61 per cent, magnesia 16·65 per cent, phosphoric acid 31·16 per cent, sulphuric acid 2·16 per cent, silica 0·31 per cent, chlorine 1·62 per cent.—*Independent Journal.*

AGRICULTURE IN AMERICA: THE BEEKEEPING INDUSTRY.

BY JOHN L. DOW.

In nothing has there been greater progress displayed throughout America during the past half-dozen years than in the keeping of bees. Formerly success in beekeeping was attributed largely to "luck," and the variety of systems practised by different beekeepers was only equalled by the multiplicity of designs adopted in the construction of the hives. A specialty of the American farm, as seen today, is its apiary, as the rows of hives are called, which are marshalled along at distances of from 5 to 7 feet from each other in some convenient situation near the garden or orchard. And what arrests attention is the similarity of pattern in these square white painted hives. From California to Massachusetts one would think that the keepers of bees had obtained their hives from one maker. You find, however, that nearly every State has its own special make of beehives, but the differences are only in detail, and do not interfere with the general plan that seems to govern these square boxes. We eventually discover that keeping in America is now everywhere reduced to principles that are as much distinguished for their certainty of operation as formerly the occupation was noted for being one essentially of guesswork.

Although beekeeping to the extent of apiaries comprising from a dozen hives or so up to about 50 is general among the farms and orchards, the big bee ranche, whose proprietor devotes his whole attention to the industry, is also quite an established American concern. It is estimated that for the year 1882 there were 70,000 beekeepers in the United States, possessing among them a total of 2,000,000 hives, averaging 20 lb. of honey each, which at the low average of 10 cents per lb. represented a total of 4,000,000 dollars, besides 20,000,000 lb. of wax, worth 6,000,000 dollars, or a total for the year's crop of 10,000,000 dollars. Of these amounts, honey and wax to the value of 1,200,000 and 700,000 dollars respectively were exported for the same year. Among the beekeepers in the eastern states the work of what is called "wintering the colonies" is a very serious portion of the beekeeper's responsibility, but in the more genial and Australian like climate prevailing along the Pacific Coast, between San Francisco and Mexico, the bee industry is carried on under the most favorable conditions. In Los Angeles County, southern California, there are 200 apiaries, aggregating 12,000 hives, from which it is estimated that an average of 500,000 lb. of honey are taken annually; and one large producer, Mr. J. S. Harbison, sent through to New York on one occasion a consignment of honey and wax amounting to 10 car loads of 20,000 lb. each or 200,000 lb. in all. Among individual yields vouched for at Los Angeles is one where from a single hive during the season 566 lb. of honey was taken, some of which, owing to its purity and the superior manner in which it was got up for market, reached 50 cents per lb.

The square box form of the hives that has already been alluded to was adopted as far back as 1851, almost about the same time, by the American and German beekeepers, Langstroth and Dzeron respectively, to admit of working their movable comb improvement, an invention which has led the way to all the recent beekeeping improvements. It is strange that the complete revolution in bee management effected by the early discoveries of these two men

should only have taken place within the past few years; and it is no less notable that in 1883 the Langstroth hives are making their way all over America with little alteration in their design to those first submitted by Mr. Langstroth in 1851. Instead of the old straw hive, in which the bees were smothered previous to the honey being promiscuously tumbled out, all mixed up with larvæ, wax and broken comb, the modern hive is fitted with square frames, which can be lifted out and dropped in again at will, just as panes of glass are handled in a glazier's box. These frames are what the bees build their comb upon, and set to work at filling with "extracted" or "box" honey respectively, just as their owner may desire.

Extracted honey is that which is separated from the comb, and box honey the kind that is sold in boxes holding a pound or so of honey, and in the form that it comes from the hive. For extracted honey, full sized frames are used in the hive, but for box honey the frames are subdivided into the boxes within which the bees are to construct the honeyfilled comb in the shape intended for market. When the full frames are charged with honey, another achievement in the new beekeeping system is brought into operation, viz., the honey extractor. This is an ingenious contivance, resembling in appearance the square frame of a street lamp, the sides of which are fitted with honey-charged frames from the hives, and the whole then inserted within an enclosure like an oil drum, fitted with a tap. The apparatus, with its frames of honey, is fitted into pivots above and below, and is then swiftly rotated by a tooth and pinion attachment. The honey, by centrifugal force, is thus thrown from the frames, and is drawn off by the tap in the enclosing drum.

"Comb foundation" is another of the improvements. The bees, it appears, if left to themselves, not only occupy too much of the honey-making season in comb building, but also work up too much valuable material to suit the commercial notions of the modern bee manager. Honey-comb is made of pure wax, which the working bees exude from minute folds of their bodies in the shape of thin flakes or scales. It is estimated that every square inch of comb built by the bees is done at the expense of from 15 to 20 times its weight in honey. Thus the beekeeper resorts to comb foundation, and by saving the bee the work of making it, obtains the extra honey. A little machine with iron rollers, resembling in form the wringer in a clothes washer, is used to roll out beeswax into thin sheets of comb foundation. These are fastened on the frames, and the frames dropped into their places in the hive, when the bee proceeds at once to business.

At first, comb foundation was not a success, and it was discovered that the hitch occurred in the sheets being rolled out plain. The bees would not work because they could find no trace of cells. Then an enterprising inventor engraved his rollers, so as to stamp the sheets of beeswax with a perfect imitation of the bees 'cells, when' thenceforth, the busy little insects buckled down to work with as much satisfaction as if they had made the sheets themselves. Some bee keepers roll out their own foundation, but most obtain it from one of the many suppliers of bee-keeping requisites that are to be found all over the United States. Here is one of their advertisements:—"We are prepared to promptly fill all comb foundation orders at the following prices—one to ten lb., 55 cents per lb.; fifty lb. or over, 50 cents per lb.; 100 lb. or over, 45 cents. per lb. Our largest sheets are 12×12 inches, and run from 5 to 8 square feet to the pound. In ordering give inside dimensions of frames. If ordered by mail add 25 cents per pound to above charges for postage and extra packing; samples by mail, post paid, 5 cents."

Another triumph of the new system is the "smoker," by which the most nerveus person can handle and work among the bees with the utmost safety. Formerly a few individuals in a locality were regarded with considerable veneration, owing to their possession of a supposed mysterious influence that prevented bees from stinging. The whole art of bee taming is now found to consist in the fact that bees will not sting when filled with honey; that to get them to fill themselves it is necessary to frighten them, and that the necessary frightening is effected by puffing a little smoke into their hives. For this purpose the smoker, which is a pointed tin funnel filled with smouldering rags and having a small bellows attached, forms one of the beekeeper's indispensable tools of trade. The handy manner in which the bees can be inspected by puffing a little smoke into the hive, and then lifting out any section of the movable combs, enables the condition of the colonies to be constantly noted.

The first step on the part of new beginners in bee keeping is to post themselves in the interesting study of bee physiology by obtaining one of the numerous books on the subject. The best works among American publications are:—*King's Bee Keepers' Text Book*, *Langstroth's Bee Book*, *Quinby's New Bee Keeping*, *Roots's A. B. C. of Bee Culture*, and *Cook's Bee Keepers' Guide*. A prosperous hive or colony of bees consists of a fertile queen, a few hundred drones and about 40,000 workers. The queen is the prolific parent of the whole colony, and laying eggs is the sole end of her existence. In the height of the honey gathering season, and under favorable circumstances, the queen will deposit about 3000 eggs per day. She is distinguished from the other bees by being larger and having smaller wings. The drones are bulkier than the queens, but shorter, and have large wings, but are destitute of a sac for carrying honey and incapable of performing the duties of the workers. Their business is the fertilisation of the queens, and as impregnation is effected while on the wing, the drones leave the hive in considerable numbers about noon on fine days, and are followed by the young queens. When the service of fertilisation is supposed to be accomplished the workers drive out the drones and keep them out till they die of starvation.

One of the many advantages of working the movable comb hives is that all excess of drone comb (which differs from the honey comb) can be removed, and the production of useless consumers thus kept in check. The workers are the smallest in size of the three classes of bees, and although females are incapable of fertilisation by the drones, so that, although they occasionally lay eggs, these never produce working bees. Upon the workers devolve all the labor of building comb, collecting the honey and feeding the queen and brood. Their average age varies from a few weeks in summer to from six to nine months during the remainder of the year. The queen's average age is from three to four years, and should her death occur the workers construct large cells, supplying them with what is described as "royal jelly," so that the eggs or larvæ that otherwise would have produced worker bees are developed into queens. Only one queen is allowed to remain in each hive. The queen usually leaves the hive when about five days old to meet the drones in the air for fertilisation, which, being accomplished, serves her for life, as she seldom afterwards leaves the hive, excepting in company with her first swarm.

The average time from the laying of the egg to the appearance of the perfect insect is for the queen 16, for the worker 21, and for the drone 24 days respectively. The cells in which the workers are reared are the smallest in size; those for the drones nearly one-third larger, and for the queen still larger and of peculiar form, requiring as much material for their construction as 50 worker cells. In strong colonies, having plenty of stores, the queen will often deposit eggs during every month in the year, the least brood being during the three winter months. On the approach of spring an increase of brood rapidly sets in, and the bee keepers prepare for their annual harvest of swarms and surplus honey. From three to ten queen cells are generally constructed in each hive, and in about eight days after the first queen leaves with the first swarm the next queen is ready to emerge from her cell.

An important feature in connection with the movable comb system of bee management consists in the old chance method of swarming being supplanted by what is called arrificial swarming. Instead of the bees being left to swarm naturally, with the risk of being lost, the swarming is conducted at the will of the operator by the removal of the queen to a new hive, where she is followed in the most docile manner by the swarming bees. Another important advantage that the new system of beekeeping affords consists in what is called nucleus swarming, by which a queen is reared amid a small cluster of bees in a separate hive until she matures and becomes fertilised, when the hvie that is to be swarmed is shifted, and the nucleus hive put in its place. In this way the surplus bees from the shifted hive go out as usual, to their work of honey gather-

ing, and according to the law which directs them back to the exact spot of their old habitations, take possession of the new hive, and continue their operations under the new queen that they found established there to receive them. The chief gain made by this expedient is one of time, a commodity that is of special value during the honey season.

The introduction of a fertile queen to a colony is often in this way effected a fortnight earlier than they would swarm naturally, and this in a large apiary amounts to a very considerable aggregate gain. Sometimes the facilities presented by the movable comb system are called into requisition for quite a contrary operation, viz., the prevention of swarming when an increased amount of honey may be desired instead of multiplied stocks. When this is the case the frames are lifted out until the queen is found, when one of her wings is clipped, thus preventing her from flying away, and consequently putting a stop to the swarming. In preparing for wintering the bees also it is a common practice to join two colonies, so as to get through the non-producing season upon the most economical terms; a full hive, owing to being able to maintain the proper degree of warmth, requiring less food. All such handlings as these various processes involve are enabled to be carried out under the movable comb system with the utmost certainty and exactness of operation. Further details with respect to varieties of bees, bee pasturage, and other matters, will have to be dealt with in another paper.—*Leader.*

THE PINK COCONUT.—We have before us a young coconut whose outer husk presents no unusual appearance, but a cut discloses a bright pink inner husk. The nut is from a tree growing on Crow Island near the mouth of the Kelani river, which is said to have been planted by the late Mr. H. M. Fernando, one of whose sons tells us that the Sinhalese believe that the husk has some medicinal properties. The plant is said to have been got from Jaffna. Can any of our readers give us any information regarding this rare and beautiful coconut?—"Examiner." [A pink color at the ends of young coconuts we have observed. The late Dr. Gygax extracted a pink dye from the coconut husk, to celebrate which event, Mr. Taylor of Batticaloa wrote a poem in the *Observer*, "Couleur de rose."—ED.]

TEA PESTS.—The Calcutta *Englishman* says :—Considering the numerous insect pests which affect tea plants in this country, it may interest the owners and managers of tea gardens to learn that Professor Riley, of Washington, the distinguished entomologist, has just given to the world the results of long-continued experiments on the value of petroleum as an insecticide. It appears to be equally effective for all kinds of insects ; but the danger of using it as a spray to play over plants attacked by insects is lest it should prove injurious to the vegetation. Accordingly, Dr. Riley has prepared it as an emulsion, and we give his recipe in full for the benefit of our readers :—"Ordinary bar soap scraped and rubbed into paste at the rate of twenty parts of soap, ten parts of water, thirty parts kerosine, and one part of fir-balsam. This will make, when diluted with water, a thoroughly practical emulsion, which should always be thoroughly stirred before using."

THE PINK COCONUT.—The pink coconut referred to above, is called *rang-tambili* by the Sinhalese ; probably owing to the pink colour of the inner part of the husk at the upper end of the nut. The colour does not go lower down the nut, than three or four inches. There were a few years ago (and likely there are still) a couple of trees bearing this description of nut, in the village of Payagalla of Kalutara district, about three miles and a half south of that town, and near the high road to Galle. Externally the nut has the appearance of an ordinary drinking coconut, but of a slightly lighter green, and smoother surface. To a careless observer these distinctions would not be apparent. The Sinhalese, I have heard, believe the *liquid* in the nut, and not the *husk*, as the "Examiner" has it, is possessed of some medicinal properties, and use it in the preparation of some of their decoctions. I am of opinion that this *rang-tambili* is not a distinct variety of the coconut, but an accidental growth, or what may perhaps be technically known as the *sport* of nature. Now there is another description, with a green husk too, known as the *pani-pol*, or honey, or sweet coconut, the flesh of which, adhering to the inner side of the shell, is as sweet as if it was preserved in sugar, whether the nut be tender, or ripe. This too, I believe, is not a variety, and like the other, a mere caprice of nature ; or to be probably accounted for, in the former case, by some red colouring matter in the soil where the trees stand, or some sweetening substance in the latter case : for, how is it then that these two descriptions could never be propagated from seeds taken from a well-defined tree? The Sinhalese have often assured me that the experimental plant produced nothing but the ordinary green coconut. Now the way to test the fact, that these two are not varieties, is I believe, to mention the *rat-tambili*, our beautiful orange-coloured king-coconut, and the *navessi ;* the former yielding a delicious, cool, refreshing and health-giving drink, and the latter not only affords a cool refreshing beverage, but the larger part of the *husk*, the upper part of which is as tender as a carrot, is a pleasant food for the natives, and both of which are well established varieties. It would be interesting to know what W. F. has to say on this subject.—*Cor.*

PLANTING AFFAIRS IN MATALE.—As regards planting affairs, this year promises to be one more like the old days of Matale than it has seen for some time back. Taking the district as a whole, there is a very good coffee crop indeed, and cacao also promises to be a remunerative product this year. There is very little tea planted in this district, that product here being only in the experimental stage. It is perhaps natural that in the oldest and best coffee district in the island planters should be loth to forsake their old product for its rival tea. Cinchona cultivation is not carried on largely here, though some estates grow a good deal, but a little of nearly every product Ceylon will produce is as a rule to be found on every estate. Coffee is still king here, but he is supported by cacao cinchona, tea, cardamoms, rubber, vanilla, pepper, sapan. In the limited time at my disposal I was only enabled to pay a visit to one estate, and that the nearest to the town, Wariyapola. This is a large and well-cultivated estate, on which all the products mentioned above are grown under the superintendence of Mr. Dickenson. There are no no signs of leaf-disease here, and the bushes are loaded with berries, so that a bumper coffee crop is expected. Cacao was looking very well, at least those trees which had any shelter : those exposed were not doing so well. Mr. Dickenson believes in shelter for cacao, and his opinion seems to be borne out by results, though on the way up this morning. I heard a planter at Kadugannawa declare that cacao would not do with shade. Tea has only been planted on this estate very recently, and only about 20 acres are opened. A large acreage of rubber of 8 or 10 varieties is looking extremely well, but they are too young yet for general tapping. Besides these, this estate produces cinchona, vanilla, pepper, cardamoms and sapan, and all are doing fairly well. Rain is badly wanted, only 19 inches having fallen here since the beginning of the year as against 39 inches last year and an average of 28 inches. There has not been the slightest sign of the monsoon in this district, except the south-west wind. Today it has rained rather freely, but only intermittently. My impression from what I have seen and heard is that planting affairs in Matale are this year very promising, and that these anticipations may be realized it is "devoutly to be wished."

CEARÁ RUBBER.

For some time back the facts reported in regard to the growth of Ceará rubber trees and the amount of gum obtained from them under every conceivable mode of treatment have tended to but one conclusion, that the cultivation of this "new product," at least, would not pay. Our readers have seen proofs of the active and intelligent interest Mr. Gilliat has taken in the culture of the plant and the collection of its product. To facilitate the latter process Mr. Gilliat invented an instrument calculated to ensure success, had success been possible. But all experiments have had but one termination, and, now that Ceylon is about to lose and Queensland to gain the presence of the intelligent and enterprising gentleman to whom we have referred, we have his authority for announcing a failure so complete in the rubber cultivation, of which he has had charge, that the order has been issued to uproot the trees and fill in the vacant ground with tea plants. We need not say how much we regret this unfortunate conclusion of an enterprize which at one time promised so well. It is regretable for the sake of the interests of the colony as well as those of individual planters who have spent much time and money on the culture. Whether different results may be obtained with other species or varieties of the indiarubber-yielding trees, plants, or creepers, remains to be decided, but we notice that in Assam most hopes are centred in the indigenous *Ficus elastica*. This fig is common in Ceylon, but we suspect the objections to it as a cultivated product would be the long period requisite for the attainment of maturity and the few trees which would stand on an acre of ground from the habit of this fig in regard to a specially umbrageous head. Of course, an appeal lies from what we say today in regard to Ceará to other planters who have engaged in its cultivation and, finally, to Dr. Trimen. From the latter we have every reason to hope for a far more favourable verdict in regard to cacao than, we fear, he can give in the case of Ceará. While noticing the complete recovery of cinchonas and other plants affected so badly in 1882 by what was called the gum-disease, we failed to fulfil our intention of calling special attention to Mr. Jardine's statement that cacao plants which were badly diseased in 1881 are now perfectly healthy and bearing good crops of fruit. We have as much reason, therefore, to believe in the permanent profitableness of cacao as we have to doubt that ever the Ceará rubber trees can be so grown in Ceylon as to yield paying returns of gum to the cultivators.

LETTER REGARDING SPECIMENS OF CINCHONAS FROM CURATOR PHARMACEUTICAL SOCIETY.

(Museum Department.)

Pharmaceutical Society of Great Britain, 17, Bloomsbury Square, London, W. C., March 22nd, 1884.

To the Secretary of the Planters' Association, Ceylon.

Sir,—I observe in the "Overland Times of Ceylon" a paragraph in which it is stated that "the specimens (of cinchona barks) sent for the acceptance of the Pharmaceutical Society of Great Britain have so far not been acknowledged."

Until I noticed this sentence, I was not aware that your Association had forwarded any specimens to this Society.

A box arrived some time since, containing specimens of cinchona barks, apparently from the Botanical Gardens at Peradeniya, *but no letter accompanied it.* I have searched my letter-books in vain for any communication concerning it. I was therefore under the impression that the specimens had been forwarded by Dr. Trimen, under directions from the Colonial Office, and that the specimens had been given to him by two or three friends.

You will see that under this impression I reported, in our Journal, the receipt of Ceylon barks "forwarded through Her Majesty's Secretary of State for the Colonies" (June 9th, p. 1627). This Society had previously made an application to the Secretary of State for the Colonies, for a series of cinchona barks and herbarium specimens of the various species cultivated in India, Ceylon, and Jamaica. In the absence of any intimation to the contrary, it was naturally supposed by me, that the specimens referred to came in response to that request, others having been forwarded about that time from Jamaica, Darjeeling and Madras. A special letter of thanks has been forwarded to the Government Departments by the Secretary of this Society for their donations, and I therefore took no steps in the matter, supposing that a letter from the Government would have been sent to the Secretary of this Society as was the case with the other shipments.

The letter in the "Overland Times of Ceylon" (Feb. 19th, p. 205) indicates that probably a misunderstanding has occurred, which we shall be glad to rectify on hearing from you that the box in question came from your Association and not from Dr. Trimen. I append a list of the specimens it contained and have ventured to add a few notes which may perhaps be of some little interest to the members of your important Association.—I have the honor to be, sir, your obedient servant,

E. M. HOLMES, *Curator.*

P. S.—The specimens only incompletely representing the cinchonas cultivated in Ceylon, I had been in hopes that a further instalment was likely to follow and have therefore not published any remarks upon them as yet in our Journal.

Pharmaceutical Society of Great Britain,
17, Bloomsbury Square, London, W. C.

Herbarium specimens and *barks* Cinchona Ledgeriana (T. N. Christie) resembles closely a specimen of Howard's marked: "Java Ledger No. 42, Java Herbarium and also the purple-leaved Ledgeriana from Mungpoo."

It is *not* identical, however, with another specimen from Mr. Howard which is marked: "No. 10 from Mr. Moens. See Quinology p. 59, identified by Mr. Ledger as the true Rojo."

The *bark* however is *not* of Ledgeriana type, which is the more remarkable that of the Mungpoo purple-leaved plant is of the calisaya type. [We cannot understand this, except in the sense that the Mungpoo and Christie barks are simply calisaya, although the foliage is that of Ledgeriana.—ED.]

Mr. Christie's specimens of Ledgeriana and officinalis bark seem to have been taken out of one and the same parcel and look as if they were both C. officinalis crossed with C. succirubra, neither Mr. Howard nor I could see any difference between the two parcels. I cannot believe they came off the same tree as the herbarium specimens. There must be a mistake somewhere. I trust Mr. Christie may be induced to send a second series with the specimens of fruit and the bark taken off with his own hands and sent under his superintendence.

C. officinalis, Mayfield, Dimbula, leaves only.—This appears to me to be both as to bark and Herbarium specimen quite correct and to belong to the broad-leaved form. *Uritusinga* C. officinalis, Henfold, Dimbula. The Herbarium specimen is unlike any that I have, but the bark comes nearest of *F. crispa.*

C. succirubra (J. G. Macfarlane) A. and B., leaves and flowers only.—The barks appear to resemble those of Jamaica which Mr. Howard referred to *F. inbpubescens*; they are quite without the warty character met with in the Darjeeling red barks.

The Herbarium specimens I cannot offer any remarks upon, as they have no fruit and the leaves are few and not perfect.

C. calisaya (F. Saunders).—This bark is not at all of pure calisaya type but bears strong marks of being crossed with red bark. I cannot of course say whether the tree bears out this conjecture, because no specimens of the foliage or fruit were sent. I may add that when specimens are intended for analysis two parcels of each should be sent and that barks are of little value for museum

purposes unless accompanied by specimens of leaves and *fruit* off the same tree.

If it will be of any use to the members of the Planters' Association I will send a quill of the typical forms of the South American barks such as I have duplicates of. You will then be able to see how far, as to bark, divergence takes place from the type, and how far this is beneficial or otherwise as affecting the yield of quinine.

I had the pleasure of meeting Mr. Ledger at Mr. Howard's house, and I especially enquired of him whether the Ledger seeds were collected from one tree or more. In reply he distinctly informed me that they were collected from probably *about* 50 trees. It is obvious therefore that there cannot be only one form passing under this name and either the plant incompletely described in Mr. Howard's work must stand as C. calisaya variety Ledgeriana [or] as Trimen more clearly defined, Cinchona Ledgeriana. Of the latter specimens in fruit and bark off the same tree would be very valuable for reference here.

Pharmaceutical Society of Great Britain,
17, Bloomsbury Square, W. C.

Museum Department.—Herbarium specimens received from Ceylon:—

Cinchona Ledgeriana.—St. Andrew's estate, T. N. Christie, Esq.

Cinchona officinalis.—Mayfield, Dimbula (leaves only).

Do Do Henfold, Dimbula, (leaves and fruit only).

Cinchona succirubra A. and B.—Ormidale estate, J. G. Macfarlane, Esq., (leaves and flowers only).

Cinchona barks received from Ceylon.—Holbrook estate. C. succirubra 4,700 feet.—Original quill (5 years old). Renewed quill (5 months).

C. calisaya, 4,700 feet.—Original quill (7 years old), F. Saunders, Esq.

St. Andrew's estate.—C. officinalis quills (5 years old). C. Ledgerina 10·25 per cent sulphate of quinine quills (6 years old tree).

Ormidale estate.—C. succirubra (8 years old) original quill, C. J. Scott, Esq.

Mayfield estate, 4,200 feet.—C. officinals (10 years old) original.

Henfold estate.—Original quills of C. officinalis.

Wattegoda estate.—Hybrid cinchona, original quills, renewed quills.

Kotiyagala estate.—C. succirubra, original bark, shavings.

NOTES ON THE AMSTERDAM EXHIBITION.

I do not know who was the orignator of the idea of exhibiting Indian tea at the International Exhibition, held last year at Amsterdam, but the idea was a happy one, and will lead to good results. These may not be apparent at once, but will work up gradually. For an exhibition of Indian tea on the Continent, Amsterdam, the capital and commercial centre of the greatest tea drinking nation on the Continent, was well chosen, and I am glad to say our teas were well represented.

On my second visit to Amsterdam, end of June, I found our tea-room well patronized every afternoon. I had taken over with me several gentlemen interested in the article with the object of showing them our tea. By 4 o'clock every afternoon crowds of ladies and gentlemen were generally waiting for the tea to be handed round, and in and out they streamed for an hour or an hour and-a-half. In mixing amongst them and conversing with them, I found, however, soon to my horror, that most people who came to drink their cup of tea, had not the remotest idea what tea they were drinking, the tea was pronounced good and was evidently liked, as very frequently a second cup was asked for. A few knew also what they were drinking, but the great majority were under the impression that they were drinking China tea! Our acute neighbours, the Chinese, had taken advantage of this and had put up facing the entrance to the Indian Court, half-a-dozen attractive tea chests and large black boards announcing in gilt letters and pigeon English that first class "peoples tea," congo, souchong and pekoe, could be had "dirt cheap." And as the people left our tea-room, I regret to say, many a pound of China tea was purchased from our Chinese friends on the strength and quality of our tea! This could not be allowed to go on, and on my recommendation effective measures were at once taken to impress upon the frequenters of our afternoon tea, that they were regaled with Indian—British India tea. Soon after this the office became constantly beleagured by intending purchasers; permission was asked for and arrangements made to sell the stock, some 40 or 50 chests, done up in attractive packets, at fl. 1·25 per pound. Some months later I found a brisk trade established at our offices, and by the end of October every pound was sold. The tea drinking went on in the meantime most satisfactorily, and as soon as the hour struck, tea was handed round by our two Madrassees. These two men were by no means the least attraction, they looked very grand, dressed up with big turbans, and dark uniforms, edged with red and gold. It was an imposing sight to see the grand eloquent style in which they handed round tea. With the assistants of the stalls (both male and female) Tom and John, were on the most friendly, not to say affectionate terms, it was "dear Tom," and "dear John," right and left, and many a cup of tea was dispensed and indulged in after the Exhibition had closed for the day. I imagine Tom and John had rather a good time of it, though Tom complained to me that the climate did not agree with him. Perhaps it didn't, for Amsterdam, the Venice of the North, is intersected by a system of canals which, very much like Venice, at certain states of the tide, do not exactly smell like,—well say Eau-de-Cologne. The last I saw of gorgeous Tom was in November when he was preparing to return into comparative obscurity at Madras, a prospect he did not look quite joyfully forward to. He was distributing to his "friends" imposing looking cabinet-size photographs of himself as souvenirs, "cost nothing, sir," he said, "picture man sell me as Eastern prince."

Our exhibition of Tea samples, nearly all in large white glass bottles, was a very attractive one, well set up, and drew a great deal of attention and admiration, not only from the general public, but what is more to the purpose, from importers, dealers, brokers and retailers. The splendid samples of Flowery Pekoe were especially much admired, and I have been over and over again asked if we had none of that kind for sale. Had there been any available I could have got as much as 4 to 5 florins, the half kilo for small quantities, but of course there was not only nothing of that kind of tea available, but I had to explain that such tea was never made for sale, and that our saleable teas consisted of Orange Pekoes, Pekoes, Pekoe Souchongs and Broken Teas. Orange Pekoes are not much approved of, the general opinion is that they are too pronounced in flavor (medicinal they called it) and not soft enough. I am not aware whether it would be possible in manufacturing tea to substitute white tips for orange tips without any extra cost, what I mean is that the tips in the finer pekoes instead of being of an orange or yellow color, should be white, but if this can be done, a ready sale could be found for these teas, to a certain extent on the Continent at good prices. Our broken teas are not saleable on the Continent, as the consumers are very particular in having no broken or dust in what they buy. All the low kinds of Kaisow and Monings are sifted by the dealers before they can be put into retail sale, the siftings, it is true, are sold, but at very low rates. Good pekoe souchongs and middling to fine pekoes, are the teas most likely to find a ready sale, but they ought to be clean in taste. Well made Assam and Cachar teas and soft flavory Darjeelings and Kangras are much admired.

The Dutch Colonial Exhibition was put upin a separate building, adjoining the main building, and it was a really grand display. I have taken a great deal of trouble to look over their Java teas, which were likewise fully represented. What particularly struck me in Java teas, is their fine make, they are so evenly and carefully rolled. And not only the finer pekoes, but even the cheapest souchongs are closely and evenly twisted, and all have a brisk, lively black color. There is nothing of that dull greyish tint and brown color so common in Indian tea, found in the Java teas. The quality of Javas has been hitherto much inferior to our tea, their liquor is good, but nearly all have a peculiar mouldy or muddy taste, however, they are improving, and last year's importtions have been considerably better in this respect and fetched better prices than usual. I have a sample now of common Pekoe Souchong, which was sold at 45cs equal to $8\frac{3}{4}$d. or $4\frac{3}{4}$ annas per pound, English, by no means a bad tea. If I may venture an opinion, I think a good deal more attention might be bestowed by planters on the rolling of their tea, the Pekoes are of course mostly well made, although some are not, but the Pekoe Souchongs leave often a great deal to be desired, those large coarse rather open leaves of which many of the teas selling at from 11d to 13d a pound in London consist, are not liked, however good the liquor may be. They are not suitable either for being sold by themselves, nor are they good for mixing with any other kind of tea unless broken up, which I believe is generally done by English dealers, but at the expense of appearance. And there is a good deal in appearance, mor eparticularly so on the Continent, considering that so much is done now by suitable machinery, I imagine if proper attention is given, the appearance of all kinds of Indian tea might be much improved. I find all other producing countries pay much attention to this point, which ought not to be overlooked by our planters, competition is growing and we must not lose ground.

In the foregoing remarks I have freely expressed my impressions, struck by what I have learnt and seen, and I trust these notes may be of some interest to your readers.—*Indigo and Tea Planters' Gazette.*

THE INTRODUCTION OF PERUVIAN BARK INTO MEDICINE.

In the *Atlantic Monthly* for March there is an interesting paper on the discovery of Peruvian bark, and the opposition encountered in the early attempts to introduce it into medicine. The profession was not then so ready to accept new remedies as now-a days. In the case of the Countess of Chinchon (who has given the drug its botanical name), the court doctors, the surgeon-general of the army, and the chief surgeons of the Spanish ships-of-war at Callao, all appear to have opposed the administration of the Indian powder, then but little known ; and their unwillingness to experiment upon their aristocratic patient may be amply justified. But the conduct of the physicians of Charles II. nearly a century-and-a-half later, and of those of Frederick the Great over two centuries later, is not so easily excused. The bark was introduced into notice in England by an apothecary named Tudor ; but the physicians would have nothing to do with it. Evelyn records in his diary that they "would not give it to the king at a time, when, in a dangerous ague, it was the only thing that would cure him (out of envy, because it had been brought into vogue by Mr. Tudor, an apothecary). . . . . Being asked why they would not prescribe it, Dr. Lower said it would spoil their practice, or some such expression." In the case of Frederick the Great, we are told that he bitterly reviled his physicians "that they would not give him the drug of which he had heard, nor cure him of the fever, having nothing better than Pyrmont water to offer for his relief."—*Popular Science News.*

TEA AT THE HEALTH EXHIBITION.

Tea, and especially Indian tea, is having a good innings just now at South Kensington. From the time the visitor goes into the building and enters the Central Transept until he leaves, after making the tour of the ten or twelve acres of ground, it is his own fault if he fails to be refreshed with occasional cups of the fragrant beverage. It is to be had at as low a cost as one penny a cup, either at the National Training School of Cookery, at Lockhart's refreshment rooms, or at Etzenberger's tea and coffee stall ; but we cannot say we were impressed by anything but the size of the big breakfast cups in which the "tea" is served at the two latter places. At the school of cookery a small cup of fairly good China congou is vended which is drinkable, At Hand's afternoon tea-stall, where tea is offered for sale at 5s. a pound, a very decent cup of drinkable tea is obtainable for twopence—a mixture of Indian and China—or a glass of hot tea, with a slice of lemon in it, for threepence. There is a stall at the end of the Science and Art Department where Layton's tea and a biscuit is to be had for threepence, and a very neatly arranged pavilion in the grounds where Ceylon tea and coffee are sold at the same moderate price.

Indian tea in its dry state is to be seen everywhere. At Carter's seed stall there are about a dozen glass receptacles in which Indian tea is shewn. At Philip's, Sabine's, Hand's, Bowden's, Barry's and the Ceylon Tea Company's stalls are found numerous samples of the teas of India. While the Indian Tea Districts' Association has a fairly large collection of samples of teas grown in the various districts of India, some of which have been previously shewn at Amsterdam and Calcutta. In connection with the teas are interesting photographs of the various processes of manufacture, tea gardens and machinery, a full-sized Sirocco drying machine in a finished condition is erected in immediate proximity to the India Court—which is an attractive exhibit and does credit to Messrs. Davidson & Co. A good working model of Jackson's standard cross action roller is also shewn as well as a diagram of Ansell's sifting machine, with numerous photographs of the various engines and machines manufactured by Messrs. Marshall, Sons & Co.

A large uncoloured map of India 6ft. square on which the tea districts are coloured green is a very prominent feature in the Indian Court with a framed table of statistics given below.

	Area. Acres.	Out-turn in 1883. Pounds.
Assam... ...	100,000	20,000,000
Cachar and Sylhet ...	80,000	18,000,000
Darjeeling and the Dooars...	40,000	9,000,000
Kangra, Kumaon, and Dehra Doon.. ...	9,000	3,000,000
Chittagong and Chota Nagpore	4,000	1,000,000
	233,000	60,000,000

The diagram, prepared by Messrs. Gow and Wilson, illustrating the growth of the Indian tea trade during the last twenty years—showing that in 1883 the monthly consumption of Indian was nearly five million pounds, as compared with about 9¼ millions of China—has been enlarged and framed.

The annexed pamphlet is being distributed :—

India : the Home of the Tea Plant.

It is now about 50 years since the indigenous tea tree was discovered growing wild in the forests of

Assam. These forests clothe the hills which form the boundary between India and China, and it is a fair assumption that the plant or its seed was thousands of years ago exported from India into China, where it has become an important industry. Tea has not been cultivated in India for many years, the oldest company, called the Assam Company, having been founded in 1840. It is now cultivated in a dozen different parts of India, hundreds of miles apart, some being on the North East or East, others on the North West or South of India. The chief tea producing countries of India are Assam, Cachar and Sylhet, Chittagong, Chota-Nagpore, Darjeeling, Dehra Doon, Dooars, Kangra, Kumaon, Neilgherries, and Ceylon. Upwards of 240,000 acres of jungle have been cleared by our countrymen in India and planted with tea, employing over a quarter of a million people in the cultivation. Most of the 60 million lb. of tea annually sent home is manufactured by machinery—models, specimens, or drawings of the ingenious machines for rolling the green leaf, firing and sorting the tea, are to be seen in the Indian exhibit.

For several years Indian tea was little known, and not much was produced. Now (1884) India supplies fully one-third of the entire consumption of the United Kingdom. It is principally used by the trade to give strength and flavour to the teas of other countries, thereby covering their deficiencies.

It is not much known by the public who distinguish tea simply by price.

The following table shews the growth of the trade in Indian tea, and speaks eloquently of the appreciation it has secured.

In	1860,	out-turn about	1 million lbs.
,,	1864,	,,	3 ,,
,,	1874,	,,	18 ,,
,,	1883,	,,	60 ,,

The whole consumption of the United Kingdom in 1883 was 170 million lbs., of which over one-third was Indian.

You are recommended to ask your tea dealer for pure, *i. e.*, unmixed Indian tea.

Cups of Indian tea are sold inside and outside the Indian Court at threepence each, including a biscuit. Upwards of 5,000 cups have been sold in the first fortnight—which ought to help to popularize Indian tea.—*Home and Colonial Mail.*

TEA IN VICTORIA.

The latest and perhaps the most impudent excuse put forward by those anxious to reduce the standard quality of teas admitted into Victoria is that the exclusion of inferor descriptions wrongs the poor man, for whose special use they are imported. As it is understood that this argument has been strenuously urged on the Commissioners of Customs who have held office since the passing of the Tea Act, it may be well to show—wholly apart from other grounds upon which its fallacy could be proved—that it is absolutely untrue. Assuming that the commonest kind of tea sold in Victoria is retailed to the consumer at 1s. 3d. to 1s. 6d. per lb.—and very few persons are really found purchasing at the first named price—we have a starting point to work from which will be plain to everyone. Now a good common clean congou can be purchased wholesale at from 9d. to 9½d. per lb. in bond, the duty is 3d. per lb., making the cost to the distributor 12d. to 12½d. duty paid. Thus it will be seen there is a margin of profit to be divided between the retailer and middle house from which he purchases of from 25 to 50 per cent. a return, one would think, sufficient to satisfy both. Apparently this is not the case, for the Tea Act and the authorities, as well as that section of the press who are opposed to the wage earning portion of the community being duped, are railed against as offering obstacles to the admission of teas worth from 4d. to 5d. per lb. The parties who take up the cry are just those who seek, not to benefit the public but their own pockets. Tea that cost duty paid 7d. to 8d. per lb. would leave 100 per cent to be divided between themselves and the retailer, and hence we have the real cause of the present outcry against law, impure and exhausted teas not being admitted.—Melbourne *Age.*

THE GENERAL FIBRE COMPANY, LIMITED.

The gentleman, formerly a planter in Ceylon, who is connected with the above Company, and who has kept us informed of the progress made, writes by this mail :—

"I last wrote you about the 1st May. As then promised, I am posting to you today some copies of our new pamphlet on our fibre-cleaning and other machinery in which we are interested. I also send a copy of Dr. Forbes Watson's lecture at the Society of Arts, with extracts from his reports to Government on rhea at the end, and which I feel sure will interest you. The pamphlet on our fibre machine gives fullest particulars up to the present date. We will shortly be at work in Belgium on hemp and flax, and I shall send you results. A considerable number of machines have now been shipped to India and will be at work soon."

The pamphlet sent to us deals not only with the "Universal Fibre Cleaning Machine" but also with a

New Patent Rice and General Grain Decorticator.

Improved Emery Patent Saw Cotton Gin, with New Patent Condenser.

New Patent Safety Capstan Bullock Gear.

Improved "Persian Wheel" Water Lift.

So that the Company have laid themselves out for the provision of machinery for very various purposes. They also receive fibre for disposal As our readers are aware, there is no question of the fibre machine with the aid of a jet of cold water doing its work well and turning out a beautifully clean fibre. The difficulty in Ceylon, as elsewhere, has been to get paying quantities cleaned in a day. The Company truly state that much depends on the percentage of fibre in the substance operated on, the adjustment of the machine and the expertness of the workmen employed. Where the percentage of fibre runs from 3 to 5 per cent, the chances of paying results are good if other conditions are favourable ; but where, as in the case of plantain stems, the fibre is not equal even to 1 per cent, it is worse than useless to persevere in attempts to obtain paying results. The Company enumerate the chief substances from which an appreciable percentage of fibre can be obtained :—

This machine extracts and cleans the fibre of the Rhea, Jute, Hemp, Agave, Pine-apple, and New Zealand flax plants, as well as all other fibre-producing stalks and leaves, when operated on in the green and freshly-cut state.

The fibres of the great majority of plants in the green-growing condition are naturally white in colour, they become discoloured subsequently from the action of their juices under exposure to the sun and air, as also during the retting process to which many of them are now subjected, and which has frequently the effect of weakening them as well. These juices or saps in the fresh-growing plants, before they have reached their full maturity, contain the various gums and colouring matters in a state of solution, and are removed by means of cold or tepid water, but hot water or steam *coagulates* and *fixes* certain of the gummy substances in them, and also *sets* the colouring matters on the fibres in a manner which often renders it impossible to prepare the fibre afterwards in a satisfactory condition.

By the new machine these juices are at once washed out of the fibre by means of a thin sheet or flattened jet of water, the quantity and force used being regulated according to the condition of the leaf or stem operated upon. This jet or stream of water plays upon the fibres, and at the same time holds them up to the action of the beaters, forming a species of elastic cushion or backing of water during the operation. In this way there is little or no waste of fibre, and the whole of the juices, together with the green bark and broken-up stalks of the stems of exogenous plants, and the pulpy and other adherent matters of endogenous fibre-yielding leaves, are at once removed. Their fibres are extracted in their natural state, and only require to be dried and baled for exportation.

These machines are already in use in India and other countries. The fibres, from the first consignment of bales delivered in London, presenting so beautifully white an appearance, were thought to have been subjected to some bleaching process; the fact being that, for the first time, the fibres were obtained in their natural state, and in the pure condition in which they exist in the plant.

The pamphlet then goes on to state that one of the important results of the use of this machine is the introduction to commerce of the fibre of *Sanseviera Zeylanica*, and it is indicated that in the majority of cases fibre should be extracted before the plants which contain them arrive at maturity. The stalks should be operated on in as fresh a state as possible. Full directions are given for the setting and working of the machine, the revolutions being from 500 to 700 per minute, according to the nature of the plant dealt with. The refuse can in some cases be used as manure, but chiefly as fuel. Patent bullock-gear for the machines as supplied by the Company is figured and described. But what our readers will chiefly want to know is what the outturn and cost of working are represented to be, and so we quote in full the portions of the pamphlet which give these details :—

The Out-turn of Cleaned Fibre.—Each machine requires two men to feed it; one on each side of the feed-table; so that while one is changing the leaves and stalks end for end, the other is cleaning his part, and *vice versa*. In this way the machine is fully occupied and there is no waste of time or water. Although the operation is simple and easily learned, experience in working the machine has largely to do with the amount of clean fibre produced. With practice, the same hands can often turn out more than three times as much as they could at first, and of course in all cases the out-turn will also depend on the diligence as well as the quickness of the individual workman. The out-turn likewise depends to a very great extent on the proportion of fibre existing in the leaves or stalks of the plants operated on. In a recent experiment carried out at Calicut in India with plantain cut down, in as the custom after the fruit has been gathered the actual quantity operated on amounted to 67 tons, and it was cleaned by the machine, fed by two men, at the rate of five tons per day of ten hours, but owing to the watery nature of the material, the actual yield of fibre when dried ready for baling only came to 98 lb. per day (or about seven-eighths per cent), whereas in another case, about the same period, in South Africa, in which agave leaves were used, the material was likewise operated on at the rate of five tons per day, but as the proportion of fibre existing in it was four per cent, the outturn would be more than four-fold that from the plantain in the instance above referred to.

Experimental working with rheea in Algeria shews that two men can clean from 30,000 to 40,000 stalks, averaging 3-ft. 8-in. to 4-ft. in length, and weighing about 110lb. per 1,000, say from 1½ to 2 tons, which should produce of dried fibre,

at 3 per cent from 100 to 135 lb.
„ 4 „ „ 135 to 180 „
„ 5 „ „ 170 to 225 „
} per day of ten hours for each single machine.

These ascertained facts shew clearly the capacity of the machine for dealing with a very considerable bulk of material, as well as the dependence of the outturn upon the percentage of fibre existing in the plants operated upon.

An important result of the special action of the machine is, that there is very little or no waste of fibre, whereas in some existing processes the loss of fibre is equivalent to more than the whole cost of working this machine.

The machine, when properly worked, thoroughly cleans the fibre, which in the growing plant is usually of a pure natural white colour, and removes a large proportion of the gum, which in the case of Rhea is reduced to from 5 to 10 per cent. as against 25 to 30 per cent. usually found in hand-prepared China Grass. No further operation whatever is necessary beyond carefull drying and baling, the fibre being in the condition most suitable for transport and sale.

Then come instructions for sorting and baling the cleaned fibre, and last, though not least, the

Cost of Working.—The cost per ton (dry weight) of extracting and cleaning fibre by this machine will be mainly determined by the rates paid for labour and fuel; the facilities, climatic and otherwise, of drying; the percentage of fibre in the material operated upon, and the dexterity of the labourers employed; all these conditions may vary in different localities and with different plants.

Where water-power is available, fuel will be saved; where steam engines are already in use for other purposes, and not always employed—the power required for these machines may be obtained at a comparatively small cost. Semi-portable engines are supplied by this Company, specially constructed for the work, and to burn all therefuse (not required for manure) in conjunction with wood, coal, or other fuel.

The following estimate is based upon the best information obtainable from sources where the Machines have been in actual operation :—

Approximate cost per week of working a plant of 20 Machines, passing 5 tons of green leaves through each Machine per day, with an out-turn of 3 per cent. only of dry Fibre.

40 men working at Machines ...	at 3s	£6	0	0
12 men and boys taking Fibre to dry	„ 2s	1	4	0
Cutting of leaves and carriage to Machines, 600 tons...	„ 1s	30	0	0
Stoker and driver for engine ...		1	16	0
Fuel		4	0	0
Baling 112 bales, including hoop-iron, &c., &c. (7 bales per ton) ...	„ 3s	16	16	0
Interest and wear and tear, say 10 per cent. upon an outlay of about £3,000		6	0	0
		£65	16	0

The above will produce, say 16 to 18 tons of dry Fibre *per week*, at a total cost of £65 16s., or £4 2s 3d. per ton, for 16 tons only :

Dividend as follows :—

Cost of labour, serving the machine, about...	£0	9	0	Per ton of dry fibre.
Cost of engine-driver, stoker, and fuel ...	0	7	3	
Cost of cutting and carriage of green leaves	1	17	6	
Cost of baling dry fibre	1	1	0	
Cost of interest on cost of machinery and depreciation	0	7	6	

Intending purchasers, by adjusting prices to their own local conditions of labour and fuel, may readily ascertain the approximate cost of working in their locality; it is evident that the cost per ton will be reduced by a larger out-turn of cleaned fibre, which may amount to five or more per cent. in some of the more fibrous aloes, &c.—and in like manner the cost of cleaning will be proportionately increased by a smaller out-turn. It will be found that the out-put of the machines is largely increased after a short period of practical working—instances have occured where the first week's working was only about one-third the quantity subsequently obtained.

A list of prices, measurements and weights of machines follows. When paying results by means of the Company's machines have been obtained in Ceylon for aloes, pineapples or other substances, we shall be glad to be informed.

FINE TEA RESULTS IN ASSAM, HIGHLY ENCOURAGING TO CEYLON.

The annual general meeting of the shareholders of the Assam Company was held in London on the 9th June, and we need plead no forgiveness from our readers for commenting shortly upon the report as it appears in the *Home and Colonial Mail* of June 13th, for it gives the record of such accomplished and promised success in the cultivation of tea, as induces us to hold out the very highest hopes of even greater success to the proprietors of Ceylon gardens. Especially important was the reference made by the Chairman to the satisfactory results obtained by the use of machinery; he attributed the reduction in the cost of the tea to the introduction of machinery, and said that the Company was waiting for a good drying machine, and had come to the conclusion that Gibbs Barry's machine would suit them best. That machine accordingly would be introduced to their gardens, and the crop of 1885 would be prepared for market by its use. This is the machine so favourably mentioned by Mr. Owen some time ago, but of which there seems to be no single specimen in Ceylon. The principle of it is that trays are dispensed with and the tea is passed round and downwards through a cylinder. With the introduction of machinery Assam will not be so dependent upon its labour force. We learn that last year in the middle of tea-making the work at some of the gardens was materially hindered by an epidemic of cholera, which caused a large mortality: a heavy expenditure in bringing up fresh labour was thereby occasioned. This last sentence explains what otherwise would appear an anomaly, for the report goes on to say that "the gardens are now so well supplied with labour that if no unforseen contingency shall arise, our expenditure under that head for the two years next after 1884 will be small." Now in Ceylon an increased labour force would mean larger expenditure; but in Assam the first costs of securing labour are so enormous, that it pays to keep a larger force on the garden than present needs require than to endeavour to secure fresh labour as works increase.

The report with satisfaction notes that the demand for Indian tea continues to be good, and that it is steadily gaining a greater hold on the market. Its consumption last year represented 35 per cent of the total consumption of tea in England, and the return for the first four months of the current year shows that the percentage has now risen to 40 per cent, or considerably more than one-third of the entire consumption of the Kingdom. The following extract from the directors' report speaks for itself:—

The quantity of tea packed and despatched from our gardens during last season amounted to 256,996 lb., which is 139,839 lb. less than the superintendent's estimate, but 265,154 lb. more than was packed in the previous year. The expenditure during the year was £118,154, being £2,194 above the superintendent's estimate, This excess was caused by the epidemic of cholera, and it is less than what was estimated by the directors, as stated by them in their circular letter to the shareholders on the 1st of January last. There has been no improvement in the prices realized by our produce during the past year, our average price being 1s 1d, and we are of opinion that it is not safe to anticipate that the average price of Indian tea in the English market will be much improved in the future. The best efforts of the board are aimed in the direction of obtaining a large crop of improved quality. It will not pay to rely upon quality or quantity alone. It is from the two combined, with the lowest possible expenditure that we must look for any improvement in our prospects. The result for the year stands thus:—Tea sales, gross proceeds £139,209 13s 3d.; tea seed sold in India, £8,795 16s 10d; sundry receipts in India, £1,624 5s 9d; insterest and sundries, £102'16 8d; total, £149,732 12s 6d. Expenditure in India in rupees at par, £118,153 18s 8d; less exchange, £15,807 19s 9d: total, £102,345 18s 11d; expenditure in England, £21,369 1s 4d; total expenditure, £123,715 0s 3d; net profit, £26,017 12s 3d. The profit, therefore, this year amounts to £26,017 12s 3d, to which is to be added the sum of £238 3s 6d, balance of undivided profits last year, making a total of £26,255 15s 9d, out of which we propose to pay a dividend at the rate of 14 per cent, for the year, and to carry forward £53 7s 9d.

The above satisfactory profit was obtained in spite of the epidemic of cholera already mentioned, and a severe hail storm of unexampled severity that greatly injured the gardens in 1882. The directors proceed to state that the superintendent estimates the crop of manufactured tea for the current year at 2,672,200 lb., and the expenditure at £123,862, which makes the cost per lb. of tea stand at 11¼d, and as they state above that it is not safe to anticipate a higher average than that already obtained, viz: 1s 1d, this would leave but 2d a lb. profit over and above (as we take it) working expenses. However, they consider the estimate of crop to be less than may be fairly expected considering how well the gardens are supplied with labour and machinery.

The Chairman said—and we would draw particular attention to this—that the average yield from the Company's gardens was 339 lb. per acre of cultivation, but he should not be satisfied till they had reached 500 lb. per acre. Now if they in Assam, 700 miles from the sea-board, beset by disease, tempests, and labour difficulties, and with a yield of 339 lb. per acre, can show such paying results what ought not we in Ceylon to do with our generally salubrious climate, facilities of transport, abundant and cheap labour supply, and yields of 400 to 800 lb. per acre! and, we might add, with our averages of 1s 2d to 1s 6d.

At the conclusion of the meeting

"Several of the shareholders addressed the board as to the Company's condition and prospects, saying that it was reported outside that the ground on which the tea stood was getting exhausted and impoverished for want of manure. To this the chairman replied that 'The root of the tea plant goes down to the fresh virgin soil and is not dependant upon the surface soil.' The tea tree was like the chestnut and the ash, and would not benefit by the application of manure to the surface. This statement was questioned by a shareholder present."

We should think so! Fancy any tree not benefitting by the application of manure to the surface, especially the tea-tree, which no doubt goes down to a considerable depth, but has also innumerable surface feeders. We never heard the subsoil called the virgin soil before either.

We notice that the Jorehaut Tea Company, Limited, has also realized a profit of 14 per cent from the crop of 1883. If the two Indian Companies with all, their drawbacks can do this, we again say we ought to do much better in Ceylon.

CACAO CULTURE.

While the subject of cacao is attracting so much attention, we are glad to be able to place before our readers the following instructions drawn up by Dr. Trimen for the benefit of native cultivators, but which may be useful to Europeans also. The paper has been translated into Sinhalese and circulated amongst the people. It will be observed that Dr. Trimen's views coincide with our own as to shade not being necessary but shelter essential:—

INSTRUCTION TO NATIVE CULTIVATORS OF THE CACAO OR CHOCOLATE TREE.

1. *Localities, Soil, Climate, &c.*—Cacao is a completely tropical plant, and its cultivation should not be attempted above 2,500 feet, and only in warm situations

well sheltered from wind. Flat ground is better than sloping. The climate must be moist, but a well-marked, dry season, if not too long, is no disadvantage. The soil should be deep and well drained; good forest soil is, of course, best, but that of native gardens is generally very suitable.

2. *Planting.*—The seeds must be sown as soon as possible after they are gathered, as they quickly spoil for germination after becoming dry. Germination commences soon and proceeds very rapidly, and the young plants are very impatient of being transplanted, unless with the adoption of such precautions as will prevent any injury to their roots. Arrangements must, therefore, be made either for growing the seeds in a nursery in such a manner as to allow at least a foot between each seedling, so that they may subsequently be taken up with the earth about their roots or for sowing them singly in bamboo or other pots, or for putting two or three seeds in each place it is intended a tree shall occupy, afterwards allowing only the strongest seedling of these to remain. The last plan is the best for native cultivators. In plantations the trees should stand at from 10 to 15 feet apart, according to the richness of the soil, 12 feet being a good average distance.

3. *Cultivation.*—It is necessary to shade the seedling plants when young: this is effected by branches fastened in the ground of any tree which retains its withered leaves—as cinnamon, mera, &c. There is no occasion to provide any permanent shade in most parts of Ceylon, but shelter from wind is of great importance. Plenty of light and a free ventilation of air are essential for the production of good and abundant crops. The ground under the trees must be kept perfectly free from weeds, and may be littered with decaying leaves and other vegetable matter. Manure is very beneficial. The trees should be kept from growing higher than 10 or 12 feet, and the primary branches be encouraged to assume a horizontal direction; redundant shoots from these or from the trunk must be pinched off when young. The principal trunk and branches should be kept very clean, and great care should be taken that the small and delicate flowers are not rubbed off or injured.

4. *Gathering.*—A first crop may be expected on good soil in the third year. The fruit must be quite ripe before it is gathered; this is known by the rind having a yellowish colour when cut into. The pods should be cut off cleanly with a knife, and not too close to the stem. They can be easily split by a blow from a wooden mallet, and the seeds and pulp are then taken out and put into baskets to be carried to the curing-place.

5. *Curing.*—The seeds should be heaped together to "sweat." This may be done in pits or boxes, or better on a platform covered with coir matting; the seeds should be covered over with matting, gunny bags, or a tarpaulin. Every other day they must be thoroughly turned over until the process of fermentation has gone far enough, which will be in seven, eight or nine days; on the proper duration of this depends the goodness of the sample. The mucilage and pulp round the seeds is now ready to be washed off, and this washing requires several repetitions with plenty of water. As soon as clean they should be at once spread out on mats in the sun to dry, avoiding, however, the extreme heat of the day, and in about three days they will be fit for the market. In wet weather the drying must be done by artificial heat in the house.

When well dried the "beans" should be perfectly clean, with a thin pale cinnamon-brown skin, of one colour all through, and entirely free from damp or mouldiness.

Henry Trimen, Director, R. B. G.

The Government have offered R50,000 for the discovery of a machine or process to strip the fibre from the stalk of rhea in a way to put the produce in the market cheap, workable and plentiful. A Mr. Anderson now in Darjeeling has discovered how to do what is wanted. He has come from England to place the process and to demonstrate it before Government, and goes to Calcutta in a few days to form a syndicate to work his patent. From his specification and his specimen of results the process seems simple, cheap, and successful.—*Madras Times.*

NOTES ON TEA.

When noticing the report of the Assam Tea Company we intended to draw the special attention of our readers to the fact that notwithstanding so low an average selling rate for their teas as 1s 1d per lb. the Company were able to divide profits of 14 per cent for the year, this being equal to the average of a long series of years, in some of which the teas averaged twice the price they realized in 1883. This result was mainly due to the substitution of machinery for hand labour, and to some extent no doubt to improved means of communication. In Ceylon the tea enterprize practically begins with machinery, good means of communication and an abundant supply of labour available.

With regard to the formation of the tea-plant into a good bush from the very commencement—that is, from the first year of its field life, we notice that the *Indian Tea Gazette* has extracted the letter we had upon the subject a short time ago, together with our own editorial upon it. As there is a very large acreage of young tea now in Ceylon we think it is our duty to again record the results of our own experience. The tea on Abbotsford, some of which is now 7 and 8 years old, was allowed after the Indian fashion to grow at its own free will for the first two years without a knife being applied to it in any way, the consequence being that when it *was* cut down the bushes had attained the height of 6, 10, and even 13 feet with, in most cases, a clear single stem without a lateral under 18 or 24 inches, so that after pruning the fields presented the appearance of a manufactory of hat-pegs. By careful manipulation they were being got into shape, when at the commencement of last year by the late Mr. Cameron's *advice* they were again maltreated for a time by having their side branches regularly plucked. The ruinous results of this system being speedily perceived, however, the *advice* was at once set aside (during Mr. Cameron's life time) and the order was given and has since strictly been adhered to that no side branches (that is, of course, *below* the level of pruning) should be touched, except where they trailed on the ground or ran into the adjoining bush. The result is that bushes 5, 7, 10, and even 12 feet in diameter are common.

In dealing with young tea planted in 1881 and 1882 the superintendent of Abbotsford used the experience he had gained from the failure of the Indian method, and adopted one which he considered more suited to the (to outsiders) incredible rapidity of Ceylon growth. At 10 months he began nipping off the tops of all plants over 2 ft. 9 in. high, and continued this process till the plants were 18 months old, when he sent round six of his best podians with sharp knives to top all down to their 18 inch measuring sticks. The result is that the young fields form one sheet of uniform spreading bushes, with surfaces of from 2 ft. to 3 ft. 6 in. diameter in the case of 20 month old plants, and 3 to 5 ft. diameter in those 32 months old. We think we are at liberty to quote Messrs. Wm. Smith, G. M. Ballardie, G. A. Talbot, H. K. Rutherford, C. E. Strachan, J. Huntly Thring, and J. A. Rossiter, among a host of others, who can testify to having seen this tea for themselves.

Before passing on we take this opportunity to mention that we are more than ever convinced of the immense benefit tea renders to cinchona. Three years ago we planted up every fifth row of tea with cinchona, chiefly officinals and hybrid, and the losses are practically *nil* while the trees are now undergoing the McIver stripping process, having already had a partial shaving. That they do not materially affect the yield of tea flush is proved by the confident ex-

pectation of the superintendent to get at least 600 lb. of made tea per acre this year.

We have been very kindly favored by Mr. J. H. Barber of Blackstone estate with the following letter addressed to him by his Colombo agents, Messrs. Baker & Hall :—

Polwatte Mills, June 30th, 1884.

J. H. Barber, Esq., Blackstone.

Dear Sir,—We beg to send the following extract from our London Agents' letter which may prove useful to you :—

"We, notice, that whatever the gross weight, the tea is always the same; thus, packages weighing gross 83 lb. nett 60 lb. and gross 63 lb. nett 40 lb. and the dock charges come out ·90d on the larger and 1·05d on the smaller. If the smaller packages had the tare reduced 4 lb. then the dock charges would be also somewhat reduced viz., to ·95d per lb.

"The weight of your packages *gross* should run as nearly as possible to 59 lb., 79 lb., 129 lb., for the rates respectively for these weights are 3s 2½d, 3s 6d and 4s 6d.

"Thus a package weighing gross 79 lb. pays 3s 6d dock charges and one weighing 80 lb, pays 4s 6d, the extra 1 lb gross making 1s per package difference.

"These figures may possible interest some of your friends and we think will show that in their interests the gross weights should run as near to 126 lb. as possibly but not exceed that figure.

"To give another instance, take one half-chest weighing gross 83 lb. and netting 60 lb. at 4s 6d per half-chest, the dock charges work out per lb. of tea 54-60ths d, a chest weighing 126 lb. gross and netting say 100 lb. at 4s 6d per package would only pay 54-100ths d per lb. of tea making a difference of 4s per package."

We trust you may be able to act on these suggestions, as anything which tends to reduce the present heavy charges in Ceylon tea as compared with China and India teas is a point gained against our chief opponents.—We are, dear sir, yours faithfully, BAKER & HALL.

As a conclusion for today of these remarks upon tea, we gladly give our opinion of the trial that took place this afternoon at Messrs. J. Walker & Co.'s Works of Messrs. W. & J. Jackson's Manual or Hand-power Tea-roller. Some very good leaf (but hardly enough withered) from Carolina estate was manipulated. The box of the machine easily held its charge of 20 lb. and with four coolies working the cranks the leaf was well-rolled in 22 minutes in spite of a delay of 3 or 4 minutes to tighten up a screw. Not much description is needed of the machine for it is exactly on the same principle as Messrs. Jackson's larger ones, which are so well known, the box and table which work against each other being on good stout legs, and being set in motion by a cooly at each of the four handles attached to the machine. The motion seemed so easy that we think 6 coolies working in relays could well manage a ten hours' spell of work. Mr. Lamont mentioned that he was going to enlarge the box by an inch. In that case we think the output—counting three fills per 60 minutes—would be 100 lb. green leaf per hour, or say 1,000 lb. per day. The comparison then would stand thus :—

Rolling by hand, 1,000 lb. green leaf, takes coolies 25
Do. by hand-roller, 1,000 lb. green leaf takes coolies 6

making a saving of ... ... coolies 19

or of R6·27 per 250 lb. made tea per day, besides securing a more even out-turn. The only objection to the machine is what appears to us the very high price asked for it, R375 : but even at this figure it would repay itself in three or four months.

NOTES ON "KAPOK."

In giving the translated Circular below relating to the "Kapok" industry we beg to remind our readers of the correspondence respecting it which took place at the time of the Melbourne Exhibition. Indeed it was in consequence of the information which th Ceylon Commissioner then gave to the Austr lia merchants that the trade in it from Calcutta an Ceylon, noticed in the extract, sprang up. He f und that coir was being largely superseded for stuffing purposes by an article from Java called "kapok," and on requesting to be shown this product was amused to find it nothing other than what is known in Ceylon as the *silk* or tree cotton, which, as we have already said, he so favorably brought to the notice of the Australian public as to cause an appreciable scarcity of the commodity in the Colombo market! Mr. W. Ferguson pointed out at the time that the cotton of the red-flowered variety (*Bombax malabaricum*; Sinhalese *katu-imbul-gaha*), a tree he believed to be indigenous to Ceylon, was scant, compared to that of the silk-cotton tree (*Eriodendron anfractuosum*; Sinhalese *pulun-imbul-gaha*) which he believed to be not indigenous to our island, but introduced from the West Indies. It is interesting to learn from the *Gardener's Dictionary* that *erion* means wool; *dendron*, a tree; and *anfractuosum*, winding.

The trade in this commodity is rapidly increasing, having been largely introduced into Holland, Belgium and Germany. In the last-named country, we believe, it is employed in the manufacture of gun-cotton. The matter we give below is from a circular sent to us by the firm of J. C. Klütgen of Rotterdam, and which we have had translated, as the subject matter is one which is likely to prove profitable to us in Ceylon. We notice from the papers before us that among the qualities attributed to kapok is the very important one of *insusceptibility to moths*. With regard to the concluding paragraph of our extract, we may say that while acknowledging the shortness of the staple, we do not doubt that this objection to spinning it will be overcome either by the invention of special machinery, or by uniting it with a longer stapled article. What is said of packing the kapok *dry* is one of these things that ought "to go without saying." A difficulty connected with the importation of this cotton into Holland, namely its great bulk has been overcome by the construction of a kapok press. The seeds we know yield a good oil, and cotton-cake as a food for cattle is commonly used in Ceylon.

In Java, the trees are pressed into the service of Government by having the telegraph wires affixed to them, and a correspondent wrote to us some time ago from Bantam to say that the kapok was the best tree to grow pepper upon.

With regard to the profitableness of the cultivation we see it stated that the returns of a bouw (somewhat over 2 acres) of land is about 400 florins (or rupees). This would be at the rate of say £15 per acre, a very handsome return as matters go now-a-days.

(Translated from the Dutch for the "Ceylon Observer.")

KAPOK.

(Eriodendron anfractuosum.)

The article *kapok*, at present an article of commerce, comes for the most part from Netherlands East India. During the last few years, the export to this country has become of importance, as will appear from the following statistics :—

	Per ½ kilo.	Per ½ kilo.
1877—14,093 bales, average price	of uncleaned 15c,	of cleaned 36c.
1878—10,519 " " "	11c "	35c.
1879—12,050 " " "	15c "	42c.
1880— 6,479 " " "	16c "	45c.
1881— 9,991 " " "	17c "	45c.
1882—28,032 " " "	11c "	40c.

In our country the demand is extending greatly, and in Germany and Belgium also the consumption

is increasing. A difficulty, and indeed a great difficulty, in the importation of kapok exists in its great bulk, the cost of transport being relatively very high, and it is almost impossible to ship kapok by steamer. This difficulty has now been overcome by the kapok press newly constructed by the firm of Stork & Co. at Hengelo. According to the calculation of this firm a bale of 65 kilos will show a saving in freight of *f*17, or 26c per kilo. The average price of cleaned kapok standing at 40c; this makes a difference of 30 per cent. The profit consists, however, not only of the difference in price, but in the possibility of shipping *regularly* by steamer, by which the great fluctuations in the market price would be prevented, which have exercised an unfavourable influence on the placing or the import of this article, especially in foreign countries, and especially on the rent of packing-houses, which is a great burden on this article;—in the same space three times as much can now be placed.

Kapok packed in this manner has during the last two years been imported from Ceylon and Calcutta; the quality of this kapok is, however, very inferior.

In our East Indies kapok cultivation is carried on either in regular gardens or planted along the roads. Planting may be carried out either by seed or by cuttings. They are usually planted at a distance of 18 Rhenish feet. The preference is given to planting by cuttings, as a crop can then be sooner gathered. For cuttings the stem alone, not the branches, can be used. The number of fruits to a tree reaches 1,500 a year. The fruits yield:—

22 per cent clean kapok.
29 ,, seeds.
49 ,, refuse.

The return of a bouw of land is about *f*400.

The kapok is imported both in an uncleaned and cleaned state. A couple of years ago it appeared that several consignments were largely mixed with sand and earth. It cannot be sufficiently borne in mind that kapok should be packed dry: in a wet package the kapok ferments, cakes, becomes thereby discolored and loses greatly by manipulation in this country.

For stuffing beds, mattresses and furniture, kapok is the most useful of the substances hitherto used; its qualities—lightness, insusceptibility to moths, softness and elasticity—make it for that purpose preferable to feathers, wool and hair. That the amount used for stuffing is very great is sufficiently seen from the fact that nearly the whole of the import of kapok into our country is placed solely for that purpose. Kapok meets with great opposition from the dealers in horsehair, feathers and wool, because more profit is to be made in those things. For one and the same thing a larger quantity is necessary, and on account of the higher prices more is to be gained in the way of percentages; but notwithstanding this explicable opposition kapok has already left behind a very large proportion of these articles in our country and has won its spurs in Germany and Belgium. The seeds or kernels of the kapok yield a marketable oil, and the cakes made from them form a good local cattle-food.

Although kapok has for a number of years been used in India in a badly-prepared state for the filling of mattresses, and very small quantities were from time to time brought to our country, and in like manner was used in a very primitive condition for filling of beds and mattresses, my firm has for twenty years back imported the kapok in large quantities and brought it into the market.

At the same time it must be seen that kapok of these importations can be described as well prepared, cleaned and carded. In this also my firm has succeeded fully, and several manufacturers have followed in my footsteps, so that already there are eight of these establishments in our country. I may mention as a peculiarity that some years ago I had some kapok spun and woven, which articles were sent to the Colonial Museum of the Industrial Company at Haarlem. Regarding this quality of kapok Industry has not yet spoken her last word.

INDIAN AND CHINA TEAS.

We place below a very able letter by Mr. Moody of Messrs. James Henty & Co. of Melbourne, defending Indian tea from the attacks of a writer calling himself "Veritas," but known to be Mr. John Everard, a Melbourne broker who largely purchases and naturally defends low-class China tea. Portions of his letter which Mr. Moody comments on are as follows:—

With regard to the statement that "trash called tea" is imported here from China, I shall say only this, viz., that, if you place the various China kinds from north and south against teas of a corresponding nature from India China invariably carries the palm, the reason being that there is more delicacy, richness, flavour, and less harshness than in the strong Indian rival.

I may say that Indian teas are more injurious to the nervous and digestive systems than China teas is an undeniable fact, on account of their stirring and astringent qualities having a frightfully constipating effect. If anyone doubts this, let him make the acquaintance of a merchant, and get the latter to oblige him by liquoring a batch of say 30 China teas; let him taste them all carefully twice, and return next day and do likewise with the same number of Indians, and I will wager he will never repeat the latter experiment; and let him wait till the Indians are cold, and he will shrink with disgust from their filthy, curdled appearance.

Here is Mr. Moody's able and conclusive reply:—

INDIAN TEAS.

Sir,—My attention has been drawn to a letter of "Veritas" in your columns, making most astonishing statements in reference to tea, and Indian in particular. I notice his letter is full of such expressions as "I challenge," "I wager," "I say," but there is entire absence of any corroborative evidence to support these brave words.

It is useless "Veritas" denying adulteration in China teas, for the facts are against him. (See Consul Martin's report to the British Government in 1847; Mr. Robert Fortune's reports, 1853; Rev. Dr. John Henry Gray's China, 1878; and a long list of consular reports on the subject both to Great Britain and America, which resulted in the passing of the Tea Act in the latter country and the destruction of thousands of packages of tea.) All this information could be supplied if space permitted; but I will finish by giving the Customs' Laboratory returns of London for 1880. They reported that 404 samples were inferior in character and quality. "Of these 404 samples 84 were passed for home consumption, 276 were not allowed to be entered for home consumption, and 44 were condemned as unfit for human food." All this was China tea; the quantity is not given, but taking a sample as representing 200 packages (a small estimate for Victoria), it would probably amount to somewhere about 64,000 packages of tea stopped by the customs of London during the year 1880.

The *Home and Colonial Mail* (London) of 16th December 1881, puts the case very fairly thus:—"Those acquainted with the tea trade, whose knowledge and judgment are not warped by self-interest, have long been aware that the lower grades of China tea have been notorious by reason of their bad quality, the result, to a large extent, of adulteration."

Again we have the tea condemned in Melbourne by Messrs. Newbury, Dunn, and myself, fully supported by the condemnation in London by Drs. Hassall, Clayton and Bell.

It is scarcely worth while replying to "Veritas" 's assertion that he found "filings in Indian teas as long as the nail of his little finger." Probably it was a portion of the iron nails, and present through careless opening of the package. The same remark would equally apply to a piece of the bag found in the household sugar-basin.

The extract from the *Grocer re* clay in tea, was answered conclusively 11 years ago, and is no fault of the planter, but occurs in the London docks and Melbourne wharves, equally to China and Indian teas, though very rarely here. Mr. W. Roberts says, "The objectionable, if not disgusting, method of pressing down the teas, after emptying in the docks, in the chests, when refilling, by workmen's feet, clad with dirty boots or shoes, ought to be at once done away with."

The Indian Tea Districts Association have protested against the dock business over and over again, and failing to move the London Customs, have lately addressed the Secretary of State for India on the subject. The Crutched Friars warehouse now bulk and repack all tea by machinery, and I believe other dock warehouses will soon follow the same plan.

That Indian or China teas, if taken in excess, may be injurious to the nervous and digestive system is an undeniable fact, and proved in the case of China teas long before the advent of Indian teas. But if a person cannot be moderate in drinking anything, it is best to abstain altogether. I have a large family and establishment, and from the youngest child (5 years old) to the eldest (18 years) all have been drinking Indian tea and nothing else for the last four years, and we have all enjoyed splendid health during that period, and I can be confirmed by several hundred similar cases.

"Veritas" is evidently not up in the first principles of tea-tasting, which, like analysis, adopts short methods to obtain quick results, and so save time. It is probable that 4,999 persons out of 5,000 do not infuse and drink tea as the professional taster does. In fact, the most reliable test for tea is to infuse it in the home teapot, and drink it with milk and sugar, as the bulk of consumers usually do. The experienced tea-taster is continually checking and correcting his judgment in this manner; and so when he liquors, with his pretty toy cups and saucers holding about 50 gr. of tea and 4½ oz. of water, the higher test is always kept in mind, and his judgment formed from the experience so gained. If this is not done it is very like a grown-up man in a senile condition having a child's tea party all by himself.

"Veritas" 's "filthy, curdled appearance" is untrue, and won't apply, as any dictionary will point out. But some few Indian and China teas of the very finest quality present, under one condition only, and when the infusion is cold, a cloudy appearance, or as if milk had been added. Heat the liquor again, and all is bright and clear. It denotes strength, and more water or less tea should be used. Such samples are highly-valued in London, as much as 1s per lb. more being often paid over the ordinary price for other samples.

Turning to my note-book, I find that out of 7,680 different samples of Indian teas liquored, over 1,900 turned thick to a more or less degree. About 200 of these have been specially examined, and with the like result in every instance: say—50 grains of tea infused in 4½ oz. of boiling water (for five minutes) gives a bright infusion at first, but thickness in one hour's time: on again heating, gets bright and keeps bright so long as the infusion is hot. Twenty-five grains of the same tea infused in 4½ oz. of boiling water far some time, infusion bright and clear, even after four to six hours' standing.

The experiments tried with China teas were reversed, and 100 grains of tea infused in 4½ oz. of boiling water for five minutes, with similar results as to thickness, but only a very few of the China teas give so good a result.

Such experiments can be repeated by any one, and the conclusions to be drawn are unmistakable, and tend to indicate that in many cases half-a-pound of Indian tea is equal to one pound of China tea, and in liquoring with the little pots of tea-tasters, this important fact must be allowed for, or errors of judgment will mark the taster's work.

The delicious bouquet and aroma of Indian teas require no dilating upon from me. They always speak for themselves. How hard it is to part with the fallacies of our childhood! And yet the notion of crops in connexion solely with China teas in one of them, and leaves exhausted by rain is another of them. They are the pretty figments of the Chinese to cover a doubtful practice—at times dishonest.

As representing the largest importers of China teas in this market, it is unreasonable to suppose that I wish to injure this trade, but because the exigencies of our poorer colonists require a cheaper article, so it is obligatory in their interest, and as far as within our power to limit and direct the demand to pure, sound, and wholesome, if not high class tea, and further protect them, if possible, from such unwholesome rubbish as lately arrived by the "Amalfi" and other vessels, and also from any such schemes as Chapongs.—I am, etc.,

June 16th. J. O. MOODY.

—*Argus*, June 17th.

THE ENEMIES OF TEA AND CACAO.

So much attention has lately been drawn to the ravages of a disease or blight, or insect-pest, or whatever it may be, upon what is likely to become one of our chief industries, namely cacao, that we think it well to recapitulate and extract what information we have concerning such enemies as Red Spider and Tea Bug or *Helopeltis*. Before discussing these insects, however, we give the following from a book called "The Tropical Agriculturist," published in 1833 by G. R. Porter, with the hope that it may throw light on some of the points which are just now puzzling our cacao planters:—

Many of the injuries to which cacao trees are liable, arise from the attacks of insects. The most destructive of these is a small caterpillar of an ashy-grey colour, and furnished with two horns, the points of which are directed upwards. These caterpillars conceal themselves in holes, which they make in the bark of the tree: they must be picked out and destroyed by hand. On being squeezed they emit a hissing sound, resembling that which accompanies the falling of water upon heated iron, and they are so tenacious of life, that they exhibit active signs of vitality for some time after the head has been separated from the body. Another very destructive insect frequently makes its appearance at the commencement of the rainy season. This likewise takes the caterpillar form, is commonly about four inches long, as thick as a man's finger, and of various colours. These animals are so numerous in some seasons, that if allowed, they would quickly strip the trees of every appearance of foliage, and it is necessary to employ all hands for their extirpation. To complete this object effectually, as soon as the insects have put on the butterfly form, large fires should be kindled in different parts of the plantation, to which they will immediately fly, and may be readily destroyed.

Another description of insect, called by Spanish planters, *rosquilla*, flourishes in dry seasons, and must be attacked by equally vigorous measures. Others, which they call *acerredores*, resemble in form the worms first described, but are larger and black; these destroy the bark, and gnaw the wood of the trees, while the leaves and flowers form the objects of attack to the descriptions before-mentioned.

Some of these pests form their nests in the earth, and when discovered, may be effectually destroyed by pouring water into their nests, and stirring them together until the whole is reduced to a semi-fluid state.

All parasitic plants must be carefully removed as soon as they appear upon the trees, otherwise these will very quickly perish. A few hours in each week, devoted to this task, will generally suffice for its due accomplishment; but it is a work which cannot be neglected with impunity.

Cacao trees are likewise subject to a disease, which shows itself in the form of black spots, or blotches, on the bark, and which, as soon as they appear, should be carefully cut out, or the trees will quickly die. This disease does not make its appearance until the trees are in a bearing state. The disease described in the last paragraph, which appears in the shape of black spots or blotches on

the bark, seems to be the very one which followed the so-called gum-disease on Abbotsford. There these blotches covered the stems of the cinchona plants, and if cut across with a knife it was discovered that from them a canker was eating inwards to the pith through which, if it was allowed to reach it, it spread rapidly upwards and downwards, speedily producing decay and death. The only remedy seemed to be to stump the tree below the blotch, which as a rule first attacked the stem about 10 to 18 inches from its top. It was quite different from the ordinary cinchona canker, which proceeds upwards from the root, the cause of which has never yet been satisfactorily explained.

As *Helopeltis Antonii* or *theivora* (the tea-bug and mosquito blight of India) seems to be the most formidable enemy with us we give it the first place. It is described by Mr. S. E. Peal in the "Tea Cyclopædia" as follows:—

The Tea Bug has no jaws—only a sucker—belongs to the Hemiptera, wherein the wing-cases are half like wings' and used as such, and vibrate. Also, half the outer wing nearest its insertion is hardish, and the tip is membranous. In folding the wings, they cross each other; hence the winged bugs have a cross on their backs like an x, and are known from the Beetles at once, where the wing-cases join in a centre line like an I.

The "Tea Bug" is, when full grown, not unlike a large mosquito; when very young, it may, after some trouble, be seen running (often sideways) on the young leaves and stems of tea—say it is less than one-eighth of an inch long, and of pale green color.

As it grows, it turns darker (tea-liquor color), and a pair of long antennæ are developed.

Its presence may be known by the small brown punctures closely made in the younger leaves; and, as it grows, these punctures become larger and wider apart. If recently made, the spot is pale greenish brown, turning bright, and then dark brown; and when many are on one leaf, it generally dies. Eventually the Bug turns to a deep black—head, legs, antennæ, and thorax; the abdomen to opaque white. It has a small spine on the back, like a drum-stick. The damage caused by this insect is, I think, much greater (when it *does* appear) than all the previous ones together. I have seen the greater portion of a large garden so bad with it, that 35 acres of the worst part was heavily pruned in July, the Manager quite disbelieving that the "blight" was caused by any insect; and it can quite upset an estimate to the extent of probably 30 per cent. of outturn or more.

Luckily it is not steadily increasing, but seems more or less influenced by climate or season. In one year it may be bad, and in the next hardly make head at all; or it may shew in one part of a garden and not in another.

As a rule, shade favours it; it is generally worse near the edges of forest, hollas, or under large trees. The only and nearest approach to cure that I know is the removal of all shade: at the same time I am aware that it is often bad in the open as well. This will hardly sound like a "cure."

In this case I do not believe there is one, until the Bug's natural enemy (and we may be certain it *has* one) makes head. Possibly to this cause we may attribute the fact that it is not now an universal and serious enemy, for it has everything in its favour—propagates rapidly, and can elude us like the mosquito, which we might equally in vain hope to exterminate.

Another correspondent in the same work says "the distinguishing mark of the mosquito pest is the *drum-stick* standing erect between the shoulders." Others describe this peculiar spike as resembling "the head of a pin." Mr. J. Wood-Mason, who was specially deputed by the Bengal Government to investigate the nature of the insect tea-pests in Assam, found that the tea-bug is armed with a serrated ovipositor, in appearance, as in sharpness, resembling a sword: with this the insect pierces the leaves of the plant, and deposits therein the eggs that eventually cause such mischief. But the most important discovery was that the pest appeared invariably to choose the blighted portions of bushes for these operations, and that by vigorous and unremitting plucking of those parts the evil might be mitigated. This has certainly not been our experience on Abbotsford, where *Helopeltis* has put in an appearance in a mild form for the last two years on trees so luxuriating in health that they sent out double, treble, and even quadruple leaves, and are now yielding at the rate 600 lb. per acre. The small pekoe bud was first attacked, then the pekoe, and finally the pekoe souchong leaf exactly as is described above, but the superintendent has never yet been able to find a single specimen of the insect. Will someone kindly send us specimens in the various stages of growth?

Yet another correspondent of the same work notices anent mosquito blight:—

1*st*.—That it does not show itself in the cold weather.

2*nd*.—It appears first on the little buds between the leaves and stems where the new shoots come from.

3*rd*.—It develops with the young leaves in spring, and increases with them.

4*th*.—It appears yearly on the same plots.

5*th*.—It sticks more to some plots than to others that are treated the same way, and are on similar sites.

6*th*.—It is worst under tree shade.

7*th*.—Heavy rain affects it somewhat, and hot sunny weather helps it.

8*th*.—It disappears to a great extent with heavy pruning, and is worst on light pruned patches.

9*th*.—It disappears to a great extent if the jungle be allowed to grow over the bushes.

10*th*.—Nothing but cutting the bushes down so as not to leave an *eye* effects a radical cure.

11*th*.—I have never noticed it on grass land.

12*th*.—It is worst on high land.

13*th*.—It attacks the silkworm.

14*th*.—It is very fond of the *Pan* plant.

15*th*.—The Assamese call it 'Hoohouee.'

16*th*.—It breeds all through the rains.

17*th*.—You generally see two little ones together.

18th.—The insects at all stages are easily caught with the hand.

19th.—Cultivation alone is of no avail against it.

20th.—In plants that are badly attacked the pith of all the green shoots gets poisoned.

Another disease, which we have observed on Abbotsford, and of which we could not identify the cause, is attributed by an Indian planter to the innocent looking lady-bird. He writes:—"I have been troubled a great deal by a little insect of the lady-bird tribe, bright-red on top and black underneath: it scrapes among the shoot underneath the pekoe tip, causing the latter to turn black and drop down, never completely severed, but completely spoiled." We have certainly often seen the lady-birds on the tea-plants, and believing them to be harmless as their names would imply have freely allowed them to "fly away home," but with the above information in view we shall in future take good care that they or "their children do burn."

We now come to red spider, who brings us the following letter of introduction from a well known Haputale planter:—

"I send three coffee leaves which seem to me of a peculiar colour on the upper side as if they were besmeared with road-dust, and on the same surface of the leaf there are either eggs or insects of a whitish colour all over, so small that the naked eye cannot define what it really is. Could you throw any light as to what it is? If so, I shall feel obliged."

We sent the leaves to our entomological referee, who unhesitatingly pronounced the verdict "Red spider. The white powdery patches are composed of the cast skins of the insects." These pitiless little wretches must have been present in large numbers, for the leaves are simply covered with their white dust-like skins. The following description by

"Tupac Yupanqui" in the Tea Cyclopœdia is the one which coincides most closely with what we ourselves have observed in Ceylon of the habits of this voracious little arachnidan:—

The upper surface of the leaf attacked by red spider is strewn with the cast-off skins of the mites—a few entire, most broken and crumpled,—numbers of egg, and deserted yolk-bags, firmly adhering excrementa, and filaments of the finest web stretched here and there, and occasionally spun in little masses. The ova deposited on the upper surface of the leaf, the favorite nest being evidently along either side of the centre stalk. All this space is fully occupied, but eggs are also to be found scattered without any order here and there over the remaining surface of the leaf. Occasionally a few may be seen on the underside, but rarely, and on none of the leaves I examined more than half-a-dozen, evidently stray ones. The little arachnoid indeed never seems much at his ease amongst the rough fibres of the inferior side of the leaf, as his free motion and progress over its uneven, ciliated surface is rendered somewhat difficult. It is clear that the little creatures are not evolved under the leaf, though it hardly seems a hazardous conjecture to suppose that they would, when free from the ovum and possessed of activity of limb, naturally seek the shelter which the underside would frequently afford them against the elements. When the ovum has recently been vacated, the entire yolk-bag may be seen, but the upper hemisphere, which at the exit of the larval spider is partially broken off easily, afterwards becomes entirely detached, and is blown away or otherwise shaken off the leaf, so that only the inferior hemisphere remains still firmly adhering.

The white mottles to be discerned on the superior surface of the foliage are principally of two kinds; the one in dense coarser patches is a fungoid growth; and the other, in appearance like a floury dust to the naked eye, and spread generally away from the divisory stalk more towards the marginal superfice, consists chiefly of the moulted skins of the little animals, intermingled also with dried and broken yolk-bags.

The *Ovum* is spherical pellucid, and very large as compared with the size of animal which deposits it. At its primary stage (I speak of the stage in which I was able to observe it, but it is highly probable that when quite recently deposited it may have a somewhat different aspect) through the transparent outer membrane, a translucent, reddish brown, germinal vesicle, occupying fully one-third of the interior, may be discerned. It is possible though, that what I denominate the *germinal vesicle* may already have attained the embryonic state. From the upper exterior surface of the enveloping membrane a fine clear white hyaline thread protrudes, generally of a length about equal to the diameter of the egg. This thread is of a structure as though consisting of the same viscous secretion as the yolk-bag, of which it is in reality an appendaged continuation, doubtless drawn out, as it were, as the egg leaves the ovipositor. Under a moderate magnifying power the dark reddish brown embryo may be observed gradully to extend its volume, whilst it loses intensity of colour, as it absorbs the food-yolk; the vitellus, which at first was clear and bright, becomes slightly turbid, and at length the whole ovum presents an almost uniform clouded fiery pink colour, more or less intensified here and there. The yolk-bag maintains its grassy aspect. Having reached this fiery pink stage, the egg is about ready to be hatched, and shortly the covering breaks on one side, the upper hemisphere is lifted, and a plump little creature of true spider-like appearance makes his exit, leaving the clear hyaline shell empty; and, after looking about a little and taking a few slow turns to test his translucent limbs, he makes off to survey his territory. This is the red spider in his infancy; but, as he attains a very high development in the ovum he is much like his later perfect state, only that now he has not more than six legs, his color is much paler and his body—very little smaller than the ovum from which he emerged—is rounder. His legs are transparent and almost colourless.

After a short period of activity, during which his abdomen, doubtless from the food he imbibes, is always becoming darker and darker in colour and somewhat more elongated in form, he settles upon one spot—now he is almost black, excepting his cephelo-thorax, and its appendages—his skin begins to dry and shrivel, and after a period of semi-torpor, he struggles and emerges from his first moult a perfect eight-legged spider. At first he looks tender, semi-transparent and fresh, excepting, the black abdomen upon which the white bristles from a striking feature, but little by little his whole being becomes firmer and rougher and his colour more uniformly red the male may be distinguished from the female by his smaller size and more elongated abdomen.

Various remedies have been proposed. The most successful of which seem to be the plucking off and burning of all affected leaves, and the pruning of the bushes almost to the ground.

"W. B. L." ON CACAO BLIGHT.

As my experience of cacao is limited to what I have done myself on a single estate, and the results of such doings, I cannot claim to be an authority on the subject, but in answer to the requisition made for a contribution to the discussion originated in the P. A. meeting, I now proceed to state what I know.

The land I had to deal with is hilly, and in the higher parts rocky. The soil is of many qualities, running from poor gravels into deep clayey and sandy loams. Much rain falls in the course of the year, but chiefly in heavy thunder-storms, causing severe wash, little alleviated by many drains. There is no part of the land that is not exposed to wind, either direct or deflected.

In clearing this land, a few large trees were left dotted about the field, otherwise it was thrown entirely open, and planted with alternating cacao and Liberian coffee. I pass over the tens of thousands of cacao plants destroyed by white ants in the earlier stages and the replantings that followed; but many of those the white ants spared, after growing rapidly till they were from eighteen inches high, died off without any cause that I could discover. Again, when they began to branch, the tender leaves of the flushes were tossed about by the wind and dropped; the extremities withered and fresh shoots which originated lower on the branches ran the same course. The winds of the N. E. monsoon threw the plants back and they recovered more or less during the prevalence of the S. W. It was soon evident, however, that every fresh effort at recovery was made with diminished force, and, as the past season has been the most trying they have encountered, the great bulk of the plants that survived to meet it have succumbed. Wherever the soil was good and the shelter tolerable, the plants throve vigorously, came early into bearing and were very promising; but this season, the whole of those have suffered, not only to the loss of the crop, but the loss of the tree itself. I have never been able to trace to insect ravages any of the evils I have experienced in my operations: insect work I have seen as a consequence, but not as the cause. The course of events has been the same on each occasion. The winds blew off the tender leaves from the extremities of the shoots, the tender wood died back, fresh shoots were thrown out to run the same course and carry the dying-back deeper into the branches, till the whole were affected down to the stem, and, when a sucker was allowed to run up, it ran precisely the same course.

In my opinion, the conditions of success are a deep, tolerably rich loam and perfect shelter from wind, and that either of those factors without the other will lead to disappointment sooner or later. A gravelly soil, with a hard, stiff subsoil is to be avoided under any other set of circumstances; but on a suitable soil, shelter may be got up in time to save the plants even when no shelter has been provided to begin with.

As my experience is confined to a single lowcountry estate, it cannot be taken as a general rule, but I find that others have fared much the same, and some even worse than myself in these regions.

Whether shade may be an ultimate advantage, I am not prepared to say; but, judging from the little I have seen of it, it appears to me to retard the growth of young plants and defer the period of cropping, and probably the amount of the crops will be less under shade than when sheltered from wind but open to sun. W. B. L.

[Our correspondent's experience, therefore, largely confirms our views, that shade may or may not be useful, but that shelter from wind and good soil are essential. The virulence of the disease, this year, is traced to abnormal weather, while the fly is believed not to be responsible for the disease, although it attacks the trees when they become diseased. *Helopeltis Antonii* carries on its work so secretly, that of course, it is possibly responsible for much attributed to unsuitable soil and want of shelter. But all views, the result of honest and careful observation, are entitled to respectful consideration.—ED.]

COFFEE MANIPULATION.

The following article has been sent to us, specially reprinted.—ED.

If a large part of the coffee produced was left longer upon the tree it would reach the consuming markets of the world in a riper condition than at present. The result would be coffee with a better or more mellow flavor, larger bean, and of much more desirable color. The berries, however, are picked at or close to maturity; by artificial means the outer coverings, consisting of the skin of the berry, the pulp, mucilaginous surroundings and the inner skin are removed. The bean improves by age at the expense of weight, gaining in color and flavor, and therefore in commercial value. Popular prejudice accepts a dark brown or rich golden color as an evidence of age, and hence an index of drinking quality, and as a result such coffee commands a higher price.

Producers hurry their coffee to market. In many countries, owing to a lack of machinery, it reaches the shipping port poorly cleaned; in a raw or unripe condition; beans of irregular size and of varying flavor. From shipping ports it is hurried to the distributing ports of consuming countries, generally by steamer, instead of, as formerly, by sailing vessel. The result is that the coffee loses the benefits that resulted from a long sea voyage, viz.: improved color and flavor due to the fermentation or sweating process it undergoes while confined in the hold of a vessel subject to a high and moist temperature. A six month's voyage via Cape of Good Hope imparts to the large green Java bean a dark brown color, and gives to it the mellow flavor so popular with consumers.

Various artificial means are now employed to give to coffee color and flavor, some of which are legimate and others fraudulent or illegimate. In that standard authority, "Coffee from Plantation to Cup," attention is called to the report in 1879 of the chemist of the Agricultural Department, Washington, D. C., wherein he states: "The foolish demands of the people are the direct cause for the manipulation of coffee." He proved by chemical analysis that six samples of faced berries contained the following per cent. of foreign adulterants:—

	Per cent.		Per cent.
No. 1	0.68	No. 4	0.64
No. 2	0.19	No. 5	0.63
No. 3	0.08	No. 6	0 58

The mixtures used are known as orange powder; lackb powder; olive green powder. They contain chromate of lead ("chrome yellow"); sulphate of barium ("heavy spar"); burnt bones or crude bone black.

Dr. Cyrus Edson, of the New York Board of Health, has been paying special attention to the fraudulent colouring of coffee, and not only corroborates the above, but has discovered that mineral poisons are freely used by several of the companies operating in Brooklyn, N. Y., and which are to answer for their wrong practices to the Board of Health of that city. Arsenic, Venetian red, chromate of lead, ferro-cyanide of potassium, and umber are used to color the beans. The bean being porous, or spongy, absorbs the arsenic and lead so thoroughly that it is almost impossible to remove it by any roasting or chemical process. If these mineral poisons remained upon the outside of the bean it would require a white heat to destroy them; and every dealer knows that coffee is roasted in closed cylinders at a temperature which fails to volatilize any poisonous coating. It is incomprehensible how any firm of good standing can be a party to such frauds.*

The polishing of coffee, by subjecting it to friction in either upright or horizontal cylinders, is legitimate. Neither can any reasonable objection be made to the use of soap-stone in polishing. The separation of small from large beans, or the improvement of the looks of the coffee by mechanical appliances, are proper, adding to its commercial value, but there is no defense that will excuse the use of mineral poisons.

Any artificial method, whether legitimate or illegitimate, can be used to deceive, and we regret that so many reputable firms are practising fraud upon retailers by using existing processes of manipulation. Large bean coffee of Mexican, Central American, Venezuelan or other growth is made to imitate Java so closely as to defy detection except by experts. That sort of swindling has become very common, and we caution the trade against "bargains" in old brown Government Java.

Some years ago a patent was taken out for the ripening of coffee by a natural or

LEGITIMATE METHOD.

This subjects the coffee to the equivalent of a long sea-voyage through the tropics. The coffee is placed in compartments similar to the hold of a vessel, and subjected to a moist and rising temperature for about one week. The rise in temperature is gradual, and the success of manipulation depends upon the skill of the operator, whose experience enables him to determine from the condition of the green bean the degree of heat and moisture to which it can be subjected, and the time necessary to secure a certain result. The operation removes from the bean a large amount of caffeo-tannic acid, causes some varieties of the bean to expand and change color, and become mellow in flavor.

The process causes a permanent change, specimens four years old showing no loss of color. The flavor, as is natural, will continue to improve by age, notwithstanding the treatment to which it is subjected. The caffeo-tannic acid of coffee has the property of taking up oxygen and oxidizing rapidly, forming other acids. The color of the bean is supposed to depend more or less upon the changes in these acids. If live steam is allowed to act directly upon raw coffee it would partially cook it, the action being sudden and violent; but this method, once in vogue, is little practised at present.

It is unimportant to the consumer whether the changes which improve coffee are wrought on sea or land, so long as they are obtained without the use of chemicals or by any methods likely to be injurious to health. The method above described is now extensively used to give to green Java a rich, brown color, and to green Rio and Santos that much desired and beautiful golden color. It is also possible to establish and maintain a uniform standard of color. This process has also afforded additional proof that soil, climate, and condition of bean at the time of harvesting affect the flavor. It serves to lessen the rank and bitter flavor of Brazil sorts and bring some varieties of Santos and fine Rios so that they approximate in mellowness to an O. G. Java or fine Maracaibo.

In brief, fermentation under certain conditions improves some sorts of coffee. It undoubtedly improves by age, some claiming that it will gain in flavor for ten years, if kept in a dry, warm, well ventilated warehouse at as near an even temperature as possible. It loses or absorbs moisture, according to existing climatic conditions.

Buyers should guard against fraud, and when they are deceived return the goods or claim an allowance for damages.

* Any man convicted of mixing such a poison as arsenic with coffee ought surely to be sentenced to penal servitude for life.—ED.

We will cheerfully examine and report upon any samples which our subscribers will send, provided they are sufficient in quantity (not less than one pound) and come properly labeled, accompanied by a description by letter.—*American Grocer and Dry Goods Chronicle.*

DEMERARA.

Since the sailing of last packet rain has continued to fall in considerable quantities, and the rain gauges now record over 50 inches already for the year. May and June are generally looked upon as the wettest months in the year; so that, if this weather last over June, the cry will be "too much of a good thing."

The general cry from those reaping canes is short yield. This is what might have been expected after the pinching up by the drought in October and November last, coupled with the free way in which the canes flowered (arrowed).

The good old lovely canary sugar is again to the fore, and as quality (bloom) counts equal to from 2s 6d to 3s, we are not astonished to hear that the slovenly style of making American refining kinds, which call for no polish, has given way to the legitimate Demerara Crystals. We can only hope that the increased output of the higher order of production may not glut the market. What a pity that the present fiscal arrangements of our cousins prevent us from sending really highly-valued sugar to the States, in exchange for the necessaries of life in the shape of food, which we now admit duty free from that country! It is quite true the mother-country has wisely removed all restrictions, and our sugars are admitted free; but reciprocity with the mother-country does not mean what would be the effect of a similar policy on the part of the United States. The simple question of proximity points to a closer union between the West Indies and the great American Republic as most desirable. In their Western States they are in a position to supply us with breadstuffs and animal food on terms with which the free-trading Britishers cannot compete, and in the same way we can supply them with the finished and raw products of the tropical country in exchange, and this is the first principle of free trade.

Our much-prized Botanical Gardens have had a hard ordeal during the past month, and it must be disheartening to Mr. Jenman to see his fine borders and plots of rare plants completely water-logged. As Mr. Russell would describe it, the whole place has been little better than a "sheugh." We sincerely trust that the requisition of a steam pump to drain the gardens as originally intended will not be hung up until the superintendent has to stir those in authority into action by a dismal account of valuable plants destroyed for want of drainage.

There always appeared to us to be great force in Sir Henry Irving's argument that it is better to induce an immigrant to settle permanently in the colony, by offering him a piece of land in a suitable locality at a reasonable price, than to give him land on the express condition that he shall forego his claim to a back-passage, and it appears to have been well founded. The acting Government Secretary, Mr. Francis J. Villiers, stated yesterday there were numerous applications by coolies to purchase allotments of land on *Huis 't-Dieren*. And it may be regarded as tolerably certain that even an East Indian who buys land, settles upon and cultivates it, will be much less likely than another to leave the colony voluntarily. It may interest some of our readers to learn that, according to reliable statistics, the population of the colony was last year increased by immigration to the extent of 2,071, that number being the measure of the excess of arrivals over departures or "returns." There arrived :—

From India	2,537
,, Barbados	1,021
,, other places (Chinese) ...	20
Total ...	3,578

And there left the colony in 1883 :—

East Indian Immigrants ...	1,561
Chinese	251
Total... ...	1,812
Leaving a surplus of	1,766

But it will be observed in this calculation no allowance is made for the large number of Barbadian immigrants who in the natural course of events would return to their island home during the year. And we fear the number would suffice to turn the scale. But it is at least so satisfactory to note that, even with so small an immigration from India as 2,537, the number of arrivals exceeded the number of those who returned by 1,516. In other words the arrivals were to the departures as 5 to 3. And when we remember that the birth-rate among East Indian immigrants (notwithstanding the disparity of the sexes) nearly equals the death-rate—in fact was, in 1883, 25·27 per thousand, against 29·80 per thousand—the outlook is less discouraging than some honourable members of the Court of Policy yesterday appeared to imagine. —*Royal Gazette*, May 24th.

THE FRENCH PROTECTORATE IN TONQUIN.

(From the *Daily Press.*)

There are not many French colonists in the country yet, and there are no immediate signs that the number is to be increased to any very considerable extent. The few there are are not of a very estimable character from the point of view of a political economist. They are divided into two classes the *cantiniers*, the pot-house and wine-shop keepers, and the somewhat more aspiring few who do not keep *cabarets*, but sell liquor wholesale to those who do. Both of these make money, but they do not make money for France and still less for the colony. Least of all do they advance the prospects of Tonquin. With the laudable object of putting an end to the multiplication of these sorry *négociants*, General Millot has issued a proclamation. Whether, however, from a hopeless recognition of the fact that no other Frenchmen but dram sellers would come to settle in Tonquin, or with a view to control foreign traders, the edict embraces merchants of all kinds. No one is to be allowed to establish a business of any kind whatever in the country without the express permission of the Government. This is not the way to encourage the bringing of capital into the country, and Tonquin wants money even more desperately than does the French Government itself. The idea may merely be to put an end to the terrible number of drinking shops, but it seems also to be intended to keep down the establishment of foreign firms of whatever kind. The suggestion may appear ill-natured, but it seems to be borne out by a further vexatious ordinance, issued within the last few weeks. No "armed exploring parties" are to be permitted throughout the whole extent of the protectorate. This virtually means the prohibition of exploration of every kind, except such as is sanctioned by the French Government and supported by detachments of French troops. Beyond the limits of actual military occupation, no foreigner is safe unless he is armed. The word "pirate" is wonderfully misused down in Tonquin. Any native of the country is stigmatized as a pirate if he objects to the French domination of the country, and with this definition of the

word the vast majority of the population of Tonquin are pirates. They are absurdly badly armed, but twenty foot long spears and swords which bend double with every blow, are quite formidable enough weapons against Europeans who have no arms at all. The exploitation of Tonquin is therefore likely to be delayed for a considerable time. Colonists from France with money to set themselves up are devoutly prayed for, but do not seem likely to come. Meanwhile foreigners are apparently warned off, no matter how much money they may be willing to spend. This, however, is sure to right itself in time, possibly with the next Governor or Commissary-General, or if not with him, then with his successor, and administrators-in-chief of Tonquin succeed each other with even greater rapidity than Governments in France itself.

Money is wanted in Tonquin, but it must not be mistaken what it is wanted for. It is not for the cultivation of the country, for there is not a country in all this world that is more thoroughly cultivated than Tonquin as far north as Thai-nguyen and Hung-Hoa. The lower delta lands are almost wholly given over to rice, but north of the Song-eau river and the country above Sontai, Tonquin is more like a large kitchen garden than an ordinary agricultural landscape. The Tonquinese need nothing in the shape of money inducements to persuade them to work, nor do they require pecuniary assistance to extend the area of cultivation. The whole country outside of the village is in a most elaborate state of cultivation, and even in the villages themselves every available inch of ground is taken up with vegetables or tubers to season the native's bowl of rice, and areca palms and patches of sugar-cane for his solace. Capital is required merely to improve the varieties of produce, which he grows, so that the best possible results may be obtained from the smallest possible area. The country—the delta at any rate—is very densely populated, and the greater part of the harvests is required for the support of the population of the country itself. [Rice, maize, sugar-cane, cotton and tobacco are then noticed. We quote as follows :—]

Tea.—The shrub is the same as that of China, but it is not prepared in the same way and is not very palatable. A very fair green tea comes down from the upper reaches of the Red River. There are tolerably extensive tea plantations on the hills round Sontay. The French hope to attract the whole of the Puerh tea trade through the Laos country to the Red River, besides producing a rival to that famous brand on the hills bordering Yünnan.

Coffee.—Huge plantations might be established on the hills along the Song-coi river valley and those of its affluents. The French missionaries at Kesö have acclimatized the plant on the hills near this their central station and the results have exceeded the most sanguine hopes. The provinces north of of Hanoi would be the most eligible. Labour and land might be had for a mere song.

Cinnamon is grown largely, mostly the inferior kind. A very superior variety, however, is found in the hills of the southern province of Thanh-hoa, and the crops used always to be reserved for His Majesty at Hué. When, however, the French penetrate thither, which they no doubt will next October, the famous barks of Trinh-Van and Thuöng-Dong will no doubt be consigned to less royal consumers.

Indigo abounds in a good many provinces. The Tonquinese do not know how to prepare it, and therefore it is at present only used in the country. With Tirhut methods and Tirhut experience there seems no reason why there should not be a remunerative cultivation.

The *Castor-oil* plant grows in great abundance all over the country, apparently thriving equally well in the marshes and on the hills. There are huge tracts of it in the Baeninh district.

Tubers and roots of all kinds are largely cultivated and grow to an amazing size. Cabbage, and all European vegetables thrive wonderfully. The Jersey people are proud of the height of their cabbages, but the Tonquin article surpasses them in every respect, in length and breadth and thickness. A Hanoi cabbage would require a table to itself and could not be got on to any reasonable sized dish. Ground nuts, sesamum, and a considerable variety of leguminous plants are very extensively cultivated.

The *Y-dzi* (Coix exaltata) is a most useful medicinal plant. The Tonquinese call it the herb of life and health. It is one of the Pharlarides, a plant of the grass family called in France *Larme de Job*, but the Tonquin species differs from the European plant, coix lacryma, which has been introduced from India. When the skin is removed the seed may be eaten like an ordinary cereal. It has a peculiar aromatic flavour. From the roasted seeds a refreshing diuretic beverage is produced, which purifies the blood and strengthens the digestion. It is also used extensively as a remedy against the evil effects of the bad water of the mountain streams, which contain quantities of salts of copper and lead in solution. From the flour of the seeds a valuable medicinal soup is prepared. The plant gets its name from the Chinese General Ma Yuen, who conquered Tonquin in the first century of our era, and who ate very large quantities of the seed to counteract the bad effects of the climate on his constitution.

Another remarkable medicinal product of Tonquin is the Hoang-Nan (Strychnos Eautherione) which grows freely on the hills of the southern provinces of Bo-Chinh and Nghê-An. It is said to have been proved by experiment to be an efficacious remedy against the plague, paralyeis, leprosy, snake-bite and in general against all blood poisoning. European science has been greatly interested in this product of late years, and in the *Bulletin General de Therapeutique* for August 1881, there is an interesting paper by a Dr. Barthelemy, who claims great value for the plant in cases of paralysis.

Of other valuable vegetable products there is no lack. Gutta is found in abundance in the hills. So are a great variety of resinous trees, more particularly that from which the Tonquinese obtain the oil which they use for their lacquer ware, which is in no way inferior to that of Japan or Burmah. There is also a low tree which grows abundantly along the banks of the more upland streams the fruit of which distils an oil which, it is claimed, renders timber secure alike against the attacks of water and insects.

Star Anis, a valuable essential oil used in perfumery, distilled from the fruit of a tree of the Magnoliaceæ species, is also found in quantities in the northern provinces. A number of other aromatic trees and shrubs have also been seen byexperts.

Timber of all kinds is very abundant in the hills north of Thai nguyen and Hung-hoa and to the west in the provinces of Mi-Duc and elsewhere. Rose-wood, ebony, iron wood, sapan and sandal are among the more valuable varieties, I do not remember seeing the teak tree in any part of the country.

* * * *

If France were a rich country there is little doubt that Quang-yen would immediately be chosen as the port. Unfortunately the Republic is in greater pecuniary embarrassment than ever. The cable to Haiphong is only hired from the English company. Gallic pride can hardly stomach yet the construction of a railway through their rich new colony with English capital. A few years, however, will probably see it, and then, and not till then, will Yünnan be tapped.

SHWAY YOE.

Elsewhere we publish an interesting and important review of the condition and productions of Tonquin, specially written for the *Daily Press* by "Shway Yoe" whose contributions to the *St. James's Gazette* over that *nom de plume* on Burmah and its population some time ago excited considerable attention. A perusal of this article, which is the result of observations taken during the last few months in Tonquin, will afford the reader a good idea of the value of the territory just acquired by the French. Our Gallic friends, however, though they have undoubtedly gained a prize, hardly seem to know what to do with it. The expense of governing it will necessarily be great, and to develop the trade and resources of the country will require considerable capital, which does not exist there at present. So far, too, few French merchants have been attracted to Tonquin, and French capitalists are notoriously averse to investments in distant countries; much preferring low interest and undeniable security in *la belle France*. The spirit of enterprise—so far as the French nation is concerned—seems to centre in and be confined to French engineers. These gentlemen are always skilful, eager, and sanguine; they are undaunted by obstacles, and the greater the difficulties in the way the more anxious they appear to commence the work. Not so with French merchants, who for the most part stay at home. The town of Saigon has now for many years been the capital and chief port of a large French colony, but, although a large trade in rice has sprung up there, there is but one firm of French merchants in the place; and the same thing promises to be repeated in Haiphong. Wine shops and stores are multiplying in Hanoi and Haiphong, but merchants, with capital are conspicuous by their absence. It is possible, of course, that some French capitalists may be tempted to go out to Tonquin to take part in mining enterprises, which may also prove remunerative, but it is doubtful whether the mercantile community there will be much reinforced by French firms intending to carry on legitimate import and export business. The privileges which are to be secured to French traders over the frontier with the three provinces impinging on Tonquin may serve perhaps to attract some adventurous spirits, but it is more probable that the harvest—such as it may be—will be mainly reaped by British, German, and Chinese merchants. The French may, however, endeavour to prevent the fruits of their conquest eluding their grasp, and seek to handicap foreigners on the race; but they cannot shut them out entirely, and must eventually be content to see the commerce of the country developed by others if they fail to accomplish the task themselves. In any case, whether the trade of Tonquin is developed by means of French or foreign capital, Hongkong is pretty sure to benefit from it indirectly, as that colony will continue, as it has proved in the past, to be the gate to the trade of the Far East. At the same time, while there is good reason to believe that, in spite of Gallic jealousy, British merchants will participate in the advantages which the opening up of Tonquin, and free communication with Western China will confer, it will be sound policy for the British Government to seize the opportunity which the anarchy in Burmah—arising out of King Theebaw's atrocities and misrule—affords, and advance their frontier to that of China thus placing themselves in a position to claim the same commercial privileges which France is to secure in trading across the border. —*China Overland Trade Report.*

PAPAW JUICE.—Dr. Bouchat (Arch. Gén. de Med) has found that both the diluted juice and papaine have the property of digesting living tissues, normal or pathological, such as adenomata and cancers, and converting them into peptone in exactly the same way as dead ones. It seems probable that this knowledge may be turned to account in the treatment of cancer and other abnormal growths. The false membrane of croup and diphtheria removed by tracheotomy and also worms, such as tape-worm and round-worms, are attacked and digested in a few hours by the papaw juice. M. Wurtz states the papaine can digest 1,000 times its weight of moist fibrine, of which the greater part is transformed by its action into a peptone. Dr. Malcolm Morris has found this drug very useful for softening hard corns, and in cases of warts and psoriasis. The use of the fruit is believed to be beneficial in cases of impaired digestion from torpidity of the liver.

THE ENEMIES OF THE CACAO-TREE.—We have never heard of any damage being done to coffee by the tea bug, or green fly, so destructive on Indian plantations, and as yet *Helopeltis Antonii* seems to have made no serious attacks on tea in Ceylon. With cacao the case seems different, and a good deal of alarm at present prevails in regard to a black blight which attacks the pods, and in some cases the twigs, causing the latter to die back. The dying back of the branches, and in some cases the deaths of trees, we should rather feel inclined to attribute to unsuitable soil or sub-soil, tearing winds being also responsible for much damage to what seems to be a delicate tree. But we fear there can be no question that *Helopeltis* is responsible for much or most of the damage done to the pods. In Java this insect did much injury to tea and cinchona plants, but we did not hear it blamed for the black blight which was bad in 1881 on the only extensive cacao plantation in the colony. Here in Ceylon *Helopeltis Antonii* seems to have found in cacao food preferable to that which tea or coffee presents.

WE have recently come across the record of the early experiments with coffee-growing in the neighbourhood of Calcutta to which we lately made reference. It appears that the grower of the coffee forwarded a bag of it to the Directors of the East India Company, who forwarded portions of it to different produce-brokers in London, Messrs. Kiply and Brown, and W. I. Thompson. The opinion pronounced by these gentlemen was on the whole favourable, though defects in the curing of the beans were pointed out. The samples were valued at 62s. to 64s. per cwt., at a time when ordinary native Ceylon coffee was worth only 54s. to 56s. There are some remarks appended to these valuations which strike us as being not quite in accordance with facts in regard to the preparation of the beans. Speaking of the speckled appearance of the beans, one of the brokers says: "It appears to have been soaked too long in water, and afterwards to have been exposed for a long time to the rays of the sun. In the West Indies, the coffee, after having been soaked, is laid on floors covered over to keep off the rays of the sun, with the sides open to admit the air and allow the moisture to escape: in this process the greatest care is required in the constant and regular turning over of the coffee till it becomes dry." The mistake here made is in supposing that the coffee beans *removed from the inner skin* are exposed to the heat of the sun. The coffee in the West Indies has always been dried in the parchment skin which prevents the beans from being bleached. When they are perfectly hard and dry, they are placed in a "peeling mill" which removes the white thin parchment skin, after which the beans are not exposed to the sun, nor is there any occasion to do so, as they are perfectly cured in the skin, and will keep in that state for any period of time, preserving their fresh green color.—*Indian Agriculturist.*

THE ORCHARD AND FRUIT GARDEN.

Where leaf mould is in demand for pot plants, the fallen leaves of fruit trees may be raked together and put into a hole to decay. In return for thus depriving the orchard soil of a fertilising element, stable or other manure should be applied, and this may be done before digging is commenced. Fowl droppings, broken bones, woollen rags, turf as from the roadside, wood ashes and weeds, whether composted or separately, may each and all be dug in by way of supporting the fertility of the soil, a point in fruit culture of the gravest importance. Owners of fruit gardens should never allow a bone to leave their premises. There should be a hole in some part of the ground in which all such matters should be buried until the season for applying them returns. Vines are exceedingly partial to bones, they enclose them in a perfect network of roots. They are very gross feeders, and will turn to good use all animal substances, including blood and offal from slaughterhouses. These, however, are likely to be used only by large growers for market. men who also contract for nightsoil, and have all such substances properly mixed with earth, and thus deodorised. For the use of amateurs the manurial substances first named are decidedly better adapted. In peach-growing the periodical enrichments of the soil should be systematically followed up. Not an autumn should pass without an application of something more than mere vegetable manure to the ground. Bones or bone-dust should be given; the ashes of weeds or wood-ashes will also be specially useful. Precisely the same kinds of fertilisers will be serviceable to strawberries. Observant pomologists will have noted that soil long used for growing this fruit ceases to yield satisfactory crops, and that simple manuring with decayed vegetable matter fails to recuperate its productive powers. Where a healthy clay is obtainable a dressing of that will be found useful with or without the bones and wood-ashes already suggested. Clay may often be found in the subsoil, but it will usually require to be sweetened by exposure to the air; therefore when it is raised to the surface it should be spread and not be dug in for a couple of months. The better course to pursue when claying has been decided on, is to raise the clay in the spring or summer, and allow it full exposure to the sun and air until autumn, when it may be removed to the strawberry quarter and dug in. This system of strengthening sandy soils is very beneficial in all departments of the garden; it is not only more lasting than ordinary manures, but it also vastly augments the effects of those manures.—*Australasian.*

LEEKS.

The origin of the common Leek has not, we believe, been absolutely proven, but there is a general agreement among botanists that it is a peculiar form of Allium Ampeloprasum, a species wild in Southern Europe and the Mediterranean region, and naturalised in various parts of Britain. This was the view held by Linnæus, Philip Miller, Sims (*Bot. Mag.*, t. 1385), A. P. De Candolle, Gay, Alphonse De Candolle (*Plantes Cultivées*), and Regel (*Alliorum adhuc cognitorum Monographia*). The Leek, as we grow it in gardens, has nowhere been found wild, and though there seems to have been a tradition that it originated in Switzerland, we find no warrantry for the statement, which, moreover, was discountenanced both by Haller and Alphonse De Candolle, both very eminent Swiss botanists. Gerard, in the first edition of the *Herbal* (1597), p. 138, says "It is very common everywhere," but he gives no clue as to when or whence it was introduced.

Nyman, in his *Conspectus* (1878-1882), p. 735, speaks of the Leek (A. Porrum) as cultivated for culinary purposes, and as having originated from A. Ampeloprasum. In Southern Europe, however, he says it occurs here and there subspontaneously (naturalised), and is recorded in the alps of Bucovina.

Vilmorin (*Plantes Potagères*, p. 416) adopts the general view, and considers it probable that the Leek and the Allium Ampeloprasum are one and the same species, differing only in the circumstance that in the one case the cultivator's efforts have been directed to the formation of bulbs, while in the other the object has been to secure the development of long sheathing leaves.

The Leek differs from the Onion not only in the small size of the bulb, or rather in its elongate form, but also in its flat leaves, with long sheaths, and which are arranged in two rows instead of several. Moreover, while the Onion bulbs produce numerous axillary bulblets, in the Leek these are few or none. It would thus seem as if growth in length were compensated for by diminished productiveness of bulbils. Indeed, a diminished production of bulbils is a necessary consequence of the leaves being arranged in two rows only, for in a given space there are, of course, fewer leaves. We are reminded by this of what at first sight might seem widely different—we mean the "monstrosa" varieties of the common Spruce Fir, with its elongated, snake-like branches, destitute, or nearly so, of lateral divisions. Inordinate growth in length, here, as in the Leek, is accompanied by a partial suppression of the side-shoots.

We are induced to refer to the matter by the receipt from a correspondent of specimens of Leeks, some with globular bulbs, such, as Sir Joseph Hooker tells us, characterise Allium Ampeloprasum and others with long bulbs of the usual form, which we are informed are all growing together in rows from seed sown in April, 1883. We do not remember to have previously seen a similar instance of reversion.—*Gardeners' Chronicle.*

FARM MEMORANDA.

(From the *Leader.*)

ONE of the best things in the world to give a horse after he has been driven hard is a quart of oatmeal stirred in a quart of water. It refreshes and strengthens him, relieves his immediate thirst, and prepares his stomach for more solid food.

THE spattering of milk while milking may be caused either by the direction of the orifice of the teat or by some scales of skin around it by which the current is diverted. In the one case the milker can easily direct the milk into the pail by changing the inclination of the hand, and in the other case by smoothing the end of the teat with a piece of pumice stone.

OVER crowding of fowls is the cause of nearly all diseases that occur among them. There is too much strife and competition among them when kept in large numbers, and the same is true of animals. The largest breeders of fowls in the world, Hawkins, of Lancaster Massachusetts, divided his large flock into many smaller ones. He keeps over 2,000 hens on the same farm, and finds them profitable. In addition to this number of hens, thousands of chicks are annually hatched and sent to large cities.

OIL CAKE FOR YOUNG STOCK.—There is probably no better food adapted to forcing a healthy rapid growth of young stock than ground oil cake, and in fact we might say there is no better food for all kinds of stock. Old, broken down horses are made to look sleek and fat by feeding oil cake, while young stock can be forced in growth to a wonderful extent. Corn and oats are hard to digest by young stock, and often cause disease both in the stomach and mouth. We frequently hear complaints that calves and colts are not doing well, although fed on abundance of grain, and have invariably found in such cases that they were troubled either with sore mouth or constipation, or both. The first year's growth of a calf or colt is worth more than the two folowing, and should be crowded as fast as possible. During the first year the foundation is laid, and if dwarfed or cramped from starvation or neglect, the animal can only make a scrub at maturity. The time to make large frames is during the first year, and without large frames the prospect for draught or beef is by no means encouraging.—*Minnesota Tribune.*

IN the course of a lecture on China, delivered in London recently, Mr. O. V. Morgan thus described the main principles of land tenure in that country:—All land is held directly from the Crown—absolute ownership, such as prevails in Christian countries, not being acknowledged. But this does not prevent estates being held in families. Frequently farms pass from father to son. Daughters, however, never inherit land—the position of women in China in regard to land being even more disgraceful than in our own country. Lessees pay the Government a tax, the highest per acre being about 7 shillings—price being regulated by the richness of the soil, and by proximity to a market. The average tax may be taken at one shilling an acre. The total revenue from this source, including ground rent from houses, reaches some £30,000,000 annually. Th

lessee is furnished with a document, which, translated into English, means a "red deed." This is entered in the record office presided over by the local magistrates, and is acknowledged as a legal document so long as the taxes are paid. The general aim of the laws relating to farms is to secure the cultivation of all the land taken up and the regular payment of the tax, which forms the greater moiety of the entire revenue of the country. If the occupier fail to cultivate the land, or if he fail to pay the tax, he is liable to be deprived of that which by Chinese law and custom it is considered to be his duty to the state to make the best of in the common interests of all. Buildings pay a ground rent to the Government, the owner being furnished with "a red deed," as already referred to.

RAIN TREES.

Baron von Mueller has reported to the Minister of Water Supply regarding an extract taken from the *Times* dealing with the power of the Eucalyptus to absorb water from the soil. Baron von Mueller says that the remarkable case cited by the *Times* is one of the many instances in which the enormous force of the Eucalyptus to draw moisture from the ground has been clearly demonstrated. There is a similar case mentioned by Mr. J. Holdsworth, of Sandhurst, of the roots of a eucalyptus tree invading the walls of a strongly constructed tank. The widely recognised anti-malarian value of Eucalyptus depend not only on the destructive effect of Eucalyptus foliage through its oil on those micro-organisms which set up miasmatic fermentation, but also much on the exsiccating power exercised by those trees on the soil. In this respect they are almost as powerful as weeping willows, with this great difference and advantage, that their gradually dropping foliage causes no putrid decomposition, but proves in a high degree antiseptic. The two remarkable properties just alluded to, together with the extraordinary celerity of growth, have rendered some kinds of Eucalyptus, especially E. globulus, so widely famous among hardwood trees. On this subject the literature is quite extensive now. There are also records of the large quantities of aqueous fluid sucked up and concentrated, even in desert lands, by the rots of the mallee Eucalyptus. Should, however, departmental measures be under contemplation by which, through tree plantaions near reservoirs, or, perhaps along canals and natural watercourses, the temperature in the immediate vicinity is to be lessened, and strong currents of air are to be intercepted with a view of reducing evaporation, true pines and other coniferous trees would be preferable. These would withdraw less water from the soil than Eucalypts, as their foliage is more umbrageous, and, therefore, more cooling, while they are similarly antiseptic. For choice in this direction the last edition of the *Select Plants for Industrial Culture and Naturalisation* (a work of which with advantage a new and enlarged Victorian edition might be brought out) would afford some advice. As regards the "rain tree" mentioned in the *Federal Standard* of 16th April, doubtless the Albizzia Saman of tropical America is meant. This tree was in late years brought prominently under notice by the director of the Botanic Garden of Jamaica. It is particularly valuable as being one of the comparatively few trees which accommodate themselves even to brackish land. It would therefore be eligible also for our salt bush country, especially as the pods can be utilised for cattle feed. Among congeneric plants it is less tardy in growth than many others, but it may prove shy to any frost, and would perhaps not readily thrive in any tracts of country where rain is very scanty, because this tree delights in regions where the usual rainfall is not less than 30 inches annually. Plantations of the rain tree would, in accordance with general climatic laws, reduce the temperature of the atmosphere and soil, particularly during summer heat, in the locality of growth. And such arboreta would aid therefore in condensing locally the aqueous vapor into watery fluid. Nevertheless, we could not well reckon on obtaining by means of limited tree plantations any water supplies comparable to that securable by judicious storage operations, such as the Government has been carrying on for many years in various parts of the colony. However, judicious tree planting as an auxiliary measure for maintaining and augmenting water supply will soon be recommendable in connection with dams and weirs, particularly if such operations of planting or rearing trees are effected on an extensive scale. Local raising of eligible trees would economise even the yield from artesian wells, the feasibility of establising such having very long ago been publicly advocated by many in Victoria, and has more recently been practically demonstrated in Central Australia.—*Leader.*

PLANT FOOD.

The following letter appeared in the *North British Agriculturist*:—

SIR,—Your correspondent, "An Anxious Inquirer," says he has read somewhere that a healthy plant can only be raised on balance soil. I presume that what he read was the supplement distributed with some of the later copies of my small treatise on *Estimation of Phosphoric Acid.* If so, balancing—which I have in that supplement italicised, to show both its importance and the emphasis which I wished to give it—is not quite as he puts it; the exact words are, "Plant life subservient of two functions—nutrition and reproduction. In the practice of agriculture the results of these functions are subordinated to purpose, which will be best attained by applying experience derived from accurate knowledge pertaining to the *balancing* of the functions of the plant by complete or incomplete manures." As regards sulphur, it is a necessary ingredient in a manure; but it is especially important to bear in mind that many small fungi thrive in weak phosphoric acid preparations. In a former letter I spoke of water culture, and the power it has afforded experts to know what are and what are not necessary ingredients in plant food. I have, moreover, advised the proprietor of such a plant food (Detmar's), to place it before your readers in the advertisement sheet, to afford an opportunity to farmers and others to experiment therewith. I would submit, whilst bearing in mind the many and deeply interesting letters and statements which have appeared in your journal connected with our national industry—"farming;" and last, but not least, the lecter on "The Land and Laborers," by Mr. Trotter, in your last issue, that there is but one view of the land question, and that is a national one. And I have urged, both at land nationalism meetings and elsewhere that the *energy conservation* aspect of agriculture is the only view that will find favor amongst British people. This means that landlords, tenants, and community, before the land question can be peaceably settled or agriculture perform its proper functions, must understand what is ment by convertibility of force. They must also realise clearly the potential energy of a crop was a few months before the kinetic or moving energy of sunshine and heat, and that for this energy to be lost in any way is a national loss, perhaps never to be replaced.

Let me without prejudice to any class, give an example. Starting with weight of crop, the proportion which comes from the soil is about five per cent, the remainder from the air; 2 per cent is clearly what belongs to the owner of soil, and three per cent to cultivator. That which comes from the atmosphere, the 95 per cent, should represent three properties—national, cultivators, and landlords. And I submit that a basis of calculation for the latter determination exists in the excess of the units of force returned by natural causes in producing a crop, in excess of those returned by any typical machine constructed by man. (I think about 200 units are returned for one of cultivation.) It is quite clear that agricultural laborers as educated at present, that education being also paid for by the wrong class, will not be contented to work as their forefathers have worked; nor is it of national interest that they should, and this recognition is a part of the land question. It is also clear that we are not likely to derive more insight into the physiological and chemical methods and political bearings of agriculture, from their being taught the elements of agriculture, than from that which we might already derive from the work of continental *savants*, who no longer come to us to learn the science of farming, but still publish their results. What we ought to seek as a branch of our education is the capacity to apply any knowledge which human progress in any country puts before us. It will be found equally important that such a pioneer nation as the British should become alive to their relations to other nations and the methods of other nations, and should seek to possess adaptability, both in producing instruments of war and of agricultural production.—Yours, &c., J. BARKER SMITH.

A FLURRY IN QUININE.

The very low price at which quinine has been sold since the breaking up of the combination or syndicate has prevented any important speculative movement, and this article began to be looked upon as one which, though for years one of the favorite speculative articles in the drug line, would henceforth be stable in value and only be affected by the cost of raw material. The failure of the bark syndicate to control the markets of the world helped much to lead to this more satisfactory condition of the market, notwithstanding that the combination of the manufacturers of quinine was formed since the attempted bark corner failed. It appears, however, that the speculative mania for quinine was only slumbering, and that it required but a slight stimulus to cause it to break out again in full force. About a week ago some 15,000 bales of bark were offered for sale on the Continent, which were readily disposed of at prices showing a material gain over those previously realized. This was somewhat unexpected, and as the chances for an advance in quinine appeared favorable to some of the old-time operators, they have started a speculative boom, which in itself has tended to strengthen the market, irrespective of the influence of a higher market abroad for bark. Since this movement set in upwards of 75,000 ounces have been disposed of, mostly of later arrivals, and the prices paid show that the operators have full confidence in the future.

It is unnecessary to enumerate all the influences that are likely to have a bearing on the future value of quinine in this market, but it must be apparent to the careful observer that the chances for investments in a speculative way proving profitable are not more encouraging than were those made during previous speculative movements. The production of quinine has largely increased during the past few years, while the consumption has increased but slightly in this country, and in some other parts of the world shows a falling-off; and consequently the supplies of foreign and the offerings in this market have been very large, notwithstanding the low prices that have prevailed of late. The supply of quinine on hand in this and the European markets is very large, and unless an increase in the demand is developed by reason of an unhealthy season, the probabilities are that a reaction will set in and the speculators will "get left," as they have several times in the past when they allowed their judgment to be influenced by any temporary excitement in the market.

The arguments of those who profess to believe in a higher range of values for the ensuing summer months, are principally based on the fact that the price of quinine has been unusually low for some time, and that a reaction must follow, especially as the market for bark is tending upward. But *is* the market for bark tending upward? True, the sales already cited show an appreciation of values, but there is no indication of a further advance, and there is no reason why the price of bark should be higher during the summer than at present. It is well known that the supply of bark in the hands of European manufacturers is ample, and the stock in London, although largely of indifferent quality, is large. There certainly need be no apprehension of a decrease in the production, as the reports from nearly all the producing districts agree that the amount available will show an increase from year to year. It has also been asserted that with the present cost of bark quinine cannot be manufactured and sold at a profit at the prices lately ruling in this market, and that an advance must therefore follow as a natural sequence. This argument always causes a smile on the part of those who have heard this same remark when the price of quinine was twice as much as at present. Do these sanguine operators know just what is the cost of the manufacture of sulphate of quinine? We have heard no sound reason why the price of quinine should be expected to advance during the coming months, and we are therefore disposed to look upon the present flurry as being only a repetition of some of the speculative movements of the past few years.—*Independent Journal.*

FURTHER NOTE ON WARAS.

BY W. T. THISELTON DYER, M.A., C.M.G., F.R.S.

By an odd coincidence no sooner was my note on this very curious substance printed in the pages of this Journal, by the obliging courtesy of the Editor, than I received a further most interesting communication on the subject from Major F. M. Hunter, Assistant Resident at Aden. It contained a Memorandum giving the complete history of the collection of the drug with a further specimen in fruit of the plant producing it, the pods bearing the epidermal glands still undetached. There can be now no sort of doubt that the 'waras" plant is really that described by Mr. J. G. Baker, F.R.S., in the 'Flora of Tropical Africa,' as *Flemingia rhodocarpa.*

But my colleague, Professor Oliver, F.R.S., whose kindness is only equalled by his sagacity, has made the curious discovery that a *Flemingia* apparently confined to South India, *F. Grahamiana*, W. and A., is not specifically distinguishable from *F. rhodocarpa;* the pods are in fact clothed with the same peculiar epidermal glands so characteristic of that species. The "waras" plant is therefore really to be found in India after all.

In creating a new species for the "waras" plant, Mr. J. G. Baker pardonably neglected the comparison of the material he was working upon with specimens of the species occurring in so remote and botanically widely severed an area as the southern part of the Indian peninsula.

I trust that room may be found for Major Hunter's memorandum, which I append in its entirety.

Notes on "Waras" collected at Harrar in February and March, 1884.

"In the neighbourhood of the city 'waras' is not now raised from seed sown artificially, and it is left to nature to propagate the shrub in the surrounding terraced gardens. The plant springs up, among jowari, coffee, etc. in bushes scattered about at intervals of several yards more or less. When sown, as among the Gallas, it is planted before the rains in March. If the soil be fairly good a bush bears in about a year. After the berries [pods] have been plucked the shrub is cut down to within six inches of the ground. It springs up again after rain and bears a second time in about six months, and this process is repeated every second year until the tree dies. Rain destroys the berry [pod] for commercial purposes, it is therefore only gathered in the dry season ending about the middle of March. The bush grows to a maximum height of six feet and it branches close to the ground. The growth is open and the foliage sparse. Each owner has a few acres of land.

"In the middle of February, 1884, the following processes were observed:—

"The leaves [? fruiting shoots] of some plants were plucked and allowed to dry in the sun for three or four days. (The picking is not done carefully and a considerable quantity of the surrounding twigs, etc., is mixed with the berries [pods]. The collected mass was placed on a skin heaped up to about six or eight inches high and was tapped gently with a short stick about half an inch thick. After some time the pods were denuded of their outer covering of red powder which fell through the mass on to the skin. The upper portion of the heap was then cleared away and the residual reddish green powder was placed in a flat woven grass dish with a sloping rim of about an inch high. This receptacle was agitated gently and occasionally tapped with the fingers, the result being the subsidence of the red powder and the rising to the surface of the chaffy refuse, which latter was carefully worked aside to the edge of the dish and then removed by hand. This winnowing was continued until little remained but red powder. (No great pains are even taken to eliminate *all* foreign matter.) A rotl was sold in 1884 for about 13 piastres=1 rupee 10 as. nearly.

"'Waras' is sent to Arabia, chiefly to Yemen and Hadhramaut, where it is used as a dye, a cosmetic and a specific against cold. In order to use it, a small portion of the powder is placed in one palm and moistened with water, the hands are then rubbed smartly together, producing a lather of a bright gamboge colour, which is applied as required."—*Pharmaceutical Journal.*

AGRICULTURAL EDUCATION.

[The following is an extract from an address on Science and Art in connection with Agriculture, Arts and Manufactures, delivered at Barnstaple by Sir T. D. Acland, Bart., M.P., and now published in the *Journal* of the Bath and West of England Agricultural Society.]

I felt bound as a matter of respect to my agricultural friends, and still more to those teachers of science who desire to assist them, to say in a few words what I really think on the subject of the teaching of the science of agriculture in the west of England. I will not waste your time by reiterating what I said on a similar occasion two years ago at Ilfracombe, on the authority of men who are really eminent investigators of science, that the scientific explanation of the art of agriculture is still very imperfect—that, in fact, the practice is ahead of the science; and that, under present circumstances, it is impracticable for ordinary farmers safely to take science as their safest guide in the conduct of their business. I will not enlarge on what the business of the farmer is, but I will say, in passing, that if there is one business in the world which depends on practical minutiæ, it is that of farming. One reason for the opinion I have just expressed is the extreme complexity of the influences under which agriculture is carried on in this country. Secondly, if you set yourself calmly to consider the number of sciences which must be laid under contribution to raise the art of agriculture to anything like scientific perfection, it will be obvious that hardly any one man, however highly educated, and however long and large his experience, could possibly hold in his brain all the principles and facts, and qualifying or "disturbing" considerations which must be taken into account before anything like certainty in any scientific sense could be attained. Thirdly, the more profoundly a man of science has investigated the facts, the more cautious will he be in drawing conclusions with a view to giving practical rules and advice to practical men. I know something of the opinions of men who have spent their lives in trying to discover truths which may assist in guiding the farmer, and I say with some confidence that what they most desire for the advancement and also for the dissemination of useful knowledge among the cultivators of the soil is, that agriculturists should receive a higher general education. It was only yesterday morning that I received from one of the best authorities in Europe a remark on the inquiries which had been on the continent as to the various agricultural schools established there. The gentleman to whom I am alluding says that those schools would not suit England, and that what is wanted in this country is to multiply county schools. That is exactly my opinion; and I found it upon what has been said by very much abler men and more competent judges than myself. Fifteen years ago there was a plan for agricultural examination by the Royal Agricultural Society, and I was engaged in collecting information from a large number of eminent farmers and schoolmasters. Their almost unanimous opinion was that farmers required a better general education. To proceed I would say that this higher general education is advisable—1, that agriculturists' faculties of observation may be awakened; 2, that their power of recording facts and experience should be strengthened and made more precise; 3, that by working practically at some of the branches of science in a properly furnished laboratory, or on a farm specially set apart as an experimental station (I should like to see more such farms as those than there are in England at present), they should be able to put questions intelligently to men of science on matters of practice which admit of a scientific explanation; and 4, that their general habits and judgment should be matured and balanced so that they may not be misled by spurious pretenders to science, while turning to practical account the most advanced knowledge of the day supplied by specialists in science. I need only say in a single sentence that knowledge of the ordinary forces of nature—heat, light, the laws of gravity affecting the motions of solids and fluids (a very important thing for the farmer), and of gases, chemistry (inorganic and organic), physiology of vegetables and animals, a knowledge of disease—all are valuable to the farmer. But more valuable than all this knowledge will be the effect on the training of the mind, either of earnest study in the laboratory or of practical habits on the field, or in the homestead. One caution I will earnestly utter, and it applies generally. Let parents and students be careful not to confound a knowledge which is part of general education with the experience and the technical knowledge of apprenticeship. Education is one thing; apprenticeship is another. Both are needed, and both should always go side by side through life. I must apologise for going at such length into this subject; but I was really anxious to place the matter clearly before you. I wish the agricultural class to be formed in connection with the institution, and to be conducted by Mr. Pady, every success; but would again urge that they must clearly bear in mind the difference between scientific training and practical business.—*Agricultural Gazette.*

THE ADELAIDE BOTANIC GARDENS.

Dr. Schomburgk's habitually cheerful tone looms more largely even than usual at the commencement of his annual task. He has indeed good cause for saying "I have never penned an annual report with greater satisfaction than the present one," for rains so copious and widespread as those of the last twelvemonth (ending March) have seldom occurred in South Australia. The fall in Adelaide amounted to 25·400 in., against 15·742 in. during 1882. Add to that the fact of a temperate atmosphere predominating throughout the spring and summer, a paucity of hot winds, and those only of short duration, and good cause is shown for satisfaction. Summer flowers and, in fact, all florists' flowers surpassed everything previously produced; roses especially have seldom given such large and perfect flowers.

Dr. Schomburgk has devoted much time and attention to the culture of medicinal plants, both allopathic and homœopathic. Quite a large number have proved their adaptability to the country. The inquiry for some of the herbs is on the increase, especially the English broom (Cytisus scoparius); a decoction of the leaves is used for dropsy. The mullein or shepherd's club (Verbascum Thapsus); a decoction of its leaves being recommended by some American papers as a remedy for consumption; a number of persons who applied have asked for further supplies, many stating that they experienced great relief from its use. It would, of course, "be a beneficial discovery if these domestic remedies were really proved to be effective." The Virginian pokeweed (Phytolacca decandra) is much inquired for by homœopaths, by whom it is now freely used as a remedy for diphtheria. Dr. Schomburgk is assured by an authority that, through the use of this plant, a large number of children who were attacked by the disease have been saved from death. The common European dandelion (Leontodon taraxacum) is also much inquired for; its utility is well known. The culture of medicinal herbs is urged on farmers and gardeners; the demand is said to be considerable and increasing, so that the produce would find a ready market. An acre of peppermint, it is said, would yield eight or ten pounds weight of oil, worth about 40s. a pound. Common herbs, such as camomile, peppermint, lavender, dandelion, &c., would be easy of culture in the gullies, and druggists would prefer them to imported produce.

The cause of the assumed decline of native trees and shrubs where domesticated, *i.e.*, planted in gardens, may, it is thought, be found in the quick and luxuriant growth of these plants when shifted into better soil than that of their native localities, so that the altered circumstances favourable to their growth produce over-stimulation and finally exhaustion. That this is a shrewd guess at the cause is more than probable, but Hakeas, the smaller acacias, Grevilleas, callistemons, and other plants of the same class are not naturally long-lived, especially on dry shallow soil; it is only in the deep moist soils on river margins in our ranges that acacias attain the size of timber trees. Dr. Schomburgk remarks that a very peculiar phenomenon of the Australian vegetation is that most kinds of trees and shrubs when dying die from the top downwards. He might have added that exotic trees die in a similar manner; Cupressus macrocarpa and C. Lambertiana are familiar instances.

It is pleasant to learn that in the Adelaide Botanic Gardens orchids obtain a fair share of the space and attention. The collection, which is distributed in several stove-houses, has been enriched during the year by the addition of 46 species, making a total of 337 species. In the arid climate of South Australia much difficulty is experienced in growing epiphytal orchids on blocks, but

this has been met by planting them in sphaguum, or when growing them on blocks by wrapping the roots in moss. A list is given of 47 species which flowered in the course of last year. The necessity for more stove room has been urged on more than one occasion, but though new buildings have been erected from time to time, the South Australian authorities do not exercise an unwise parsimony; they permit of such further extensions as are palpably needed. A new building, therefore, is to be erected near the Victoria-house. Its dimensions are:—Length, 100 ft.; width, 50 ft., "so that the public can be admitted." The cost is estimated at £1,600. The tropical fern-house is in satisfactory condition. As regards cacti we read:—"A large collection of these plants arrived last year to replenish the species lost or stolen." The behaviour of visitors has, however, undergone much improvement, although there is room for a further abatement of the practice of carving names on trees, writing on the pedestals of statues and on the broad foliage of palms, draceenas, and anthuriums. Petty thefts of bulbous plants and others, by taking them out of pots, "are not confined to any class of society—each has its own besetting foibles." Dr. Schomburgk views with pleasure the promotion of a taste for horticulture and floriculture, especially amongst the working classes. Cottage gardens and cottagers' plants at the shows are the active evidences of this. Personally, Dr. Schomburgk is yearly receiving greater numbers of inquiries for names of plants and for other information, betokening the increasing interest felt by "cottagers" in the practice of gardening. The mammalia have been handed over to the Zoological Society, and thus from seven to eight acres of land have been set free and added to the area under trees and shrubs, and otherwise devoted to horticultural subjects. The introduction of new plants, ornamental or economical, in 1883, amounting to 326 species, exclusive of florists' flowers, has augmented the collection to 11,507 species.—*Australasian.*

VEGETABLE PRODUCTS OF BORNEO.

Some interesting notes on the products of Borneo are contained in a recently issued report. The chief of these products are gutta-percha, indiarubber, and rattans. Of the first of these the writer says:—"Various kinds and qualities of gutta-percha are afforded by various Sapotaceous trees, but the pure red Bornean gutta is yielded by Dichopsis Gutta. Other species of the genus Dichepsis, however, yield guttas which, being of inferior value, are frequently mixed by the native collectors with the more valuable red variety. The red variety is obtained from red and rough-stemmed trees, which are generally found growing among old jungle on the hill-sides to a height of from 100 to 150 feet, with a diameter to 3 feet. The natives, who roam the jungle collecting this raw product, proceed as follows:—On coming across a tree old enough to cut—one having a diameter of, say, 12 inches—they fell it, cut off the top, and ring the bark at distances of about a foot. The sap for two or three days gradually drains away, and as it does so is collected in any convenient vessels, such as leaves, coconut shells, &c., from which receptacles it is transferred to a pot and boiled with a little water for half an hour or so. The milk is boiled to prevent it from hardening on exposure to the air, as if allowed to do so it becomes comparatively valueless. It is very difficult to estimate the comparative yield of each tree, as the quantity varies so much, according to the size of the tree and time of the year—the flow of the sap being greatest when the tree is producing most leaves; but a small tree will generally yield a quarter of a picul (33 lb.), while the largest ones may yield even as much as three-quarters of a picul (100 lb.) each. The value of this red gutta varies according to its purity, from 40 dollars to 80 dollars per picul. Another species of Dichopsis (D. macrophylla) yields an inferior gutta of white colour. This species is of smaller growth (50 to 60 feet high), and differs also slightly in the foliage. It yields proportionately less gutta, often only 20 catties (26½ lb.) per ton.

INDIARUBBER, OR CAOUTCHOUC.—This is obtained from three varieties or species of rough-stemmed woody climbers, known as Manungans (Willughbeia sp.), which attains a length of over 100 feet, and a thickness of about 8 inches. The juice is obtained in much the same way as gutta, and is prepared either by boiling like gutta, or by steeping in a solution of salt. This wasteful method of collecting guttas and rubbers has naturally caused an exhaustion of the supply from the more accessible districts; the rubber trees, however, are probably not so thoroughly exterminated as the gutta tree, owing to the greater tendency of the former to be reproduced from suckers (especially when young plants are cut down), from cuttings of the stem rooting accidentally, and from the fruit, which being edible, is much sought after by monkeys, birds, wild pigs, &c.

RATTANS, OR CANES.—These are the stems of various species of Calamus, as C. Rotang; C. rudentum, C. verus, &c., which are found distributed all over the district. Two different kinds are known to the collectors by various names according to any special quality they possess. These canes are termed rattans to distinguish them from the Malacca cane (C. scipionum), the stems of which are much thicker and used, after being bronzed by heat, as walking sticks.

Under the head of "Agriculture" it is stated that the only plants cultivated in Western Borneo for exportation are the Gambier (Uncaria gambir), Pepper (Piper nigrum), and the Sago Palm (Metroxylon Sagu). Gambier and Pepper are cultivated only in the immediate neighbourhood of Sarawak, while the Sago Palm is grown on almost every river in the Sarawak and Bruuei territories, but curiously is not found in North Borneo, to the north of the Papar River, which enters the sea some fifty miles north of the island of Labuan. Its absence in North Borneo is remarkable, as it is again found in abundance still further north in the Philippine Islands. The cultivation of Pepper and Gambier is carried on together in the same plantations, and has, in the hands of skilled Chinese cultivators, proved successful; but the cultivation of the Sago Palm and the preparation of raw Sago is the only cultivation (if planting the shoots and protecting them from wild pigs can be called cultivation) congenial to Malays. From numerous enquiries made during the past few months, not only among natives who grow Sago, but of Europeans who have lived many years in Sago-growing districts in Western Borneo, the writer of the report says he feels assured that the growing of Sago by Europeans would prove remunerative. "Although," he proceeds to say, "the growth of the Palm is rapid, the tree must reach maturity before being cut, and thus ten years must elapse before any return is obtained for the capital expended; but even allowing for compound interest on the capital, the profit, by the lowest estimate, is from 20 to 25 per cent. The estimates I have met with for planting Sago are, as a rule, misleading, being evidently founded on statistics obtained in exceptionally favourable localities. The most important factors of success in growing Sago are locality and soil. I am informed that in some localities Sago trees flourish on hillsides, if so such localities must have exceptional soils, or another indigenous variety of Sago tree may exist; but practically Sago trees flourish in the level plains periodically manured with fine mud from the neighbouring hills by the overflow of the river. The presence of a whitish clay as a component part of the soil seems essential for the fullest development of the tree, one of its uses evidently being the mechanical one of retaining moisture. I have found Sago trees growing in certain localities to be between six or seven times more productive of starch than the same variety of Sago growing on soil, which, to the inexperienced eye, seemed to differ very little indeed, if at all, from that in the more productive localities. A Sago plantation demands no skilled labour, entails very little expense for up-keep, and is one of the safest investments." The necessity of waiting ten years for returns is, however, enough to deter many Europeans from cultivating this product, which is so peculiarly suited to the climate and soil of Borneo, and the preparation of which is so readily and cheaply effected by the natives of the country."

The exports of Sago in 1882 from Singapore fell much below that of the previous year, mainly due, it is said, to the low market value of Sago-flour during 1882. The quality of Sago-flour exported from Sarawak is said to be better than the average imported to Singapore.

TIMBER.—Under this head it is said that the chief wood exported is iron-wood, the botanical source of which is not known. It is of excellent quality and high value, and is said to surpass every other wood in durability. It is already becoming scarce in the vicinity of the capital, from whence its export has been prohibited, but large supplies are still obtainable.—*Gardeners' Chronicle.*

EUCALYPTOGRAPHIA.

This splendid work, probably the masterpiece of Baron Von Mueller—our Government botanist—a credit to Australia, and certainly one of the best monographs ever published, has now reached its tenth decade, and 100 species have been described and illustrated in the most ample manner. The fullest and most minute details are given of leaves, buds, flowers, fruit, seeds, organs of fructification, and every other portions of the plant; separate drawings are also given of the venation of leaves, sections of the wood, the bark, and in the present decade are drawings of the cotyledons and cotyledonar leaves of 27 species, of natural size, from living seedlings specially raised for the purpose. These drawings are of immense value in a botanical sense, for, as the author remarks:—"Great specific diversities are apparent in the cotyledonar leaves, the size and shape of which stand in relation to the dimensions and form of the cotyledons." These vary greatly: some as E. cornata are deeply lobed, others are round, some kidney-shaped, in various degrees. In E. calophylla, the cotyledons are fully an inch across, while those of others decline to little more than a line in width. Drawings of the young roots are also given, showing equally great diversity in size and branching. They are all faithfully depicted by Mr. Emil Todt, to whom the Baron accords a deserved meed of praise for the ardour he brought to bear on the furtherance of the present publication.

The first is EUCALYPTUS CORNUTA, so named from the flower lid, which attains a length of upwards of an inch. It is from the vicinity of Geographe Bay, eastward at least to the neighbourhood of Cape Arid, extending inland to the Stirling's Range. It appears that the vernacular name is "Yate." It is a tree of moderate size, rising exceptionally to 100 feet, adapted to poor soil, but preferring humid localities, thriving even in moist tropical climates, and being so rapid in its development as to have made exceptionally as much as 10 feet growth in one year. The flowers are large and showy, the stamens being 1¼ inch long. The hard and elastic wood of the "Yate" is sought particularly for cart shafts, agricultural implements and boat ribs, being for these purposes as eligible as that of E. loxophleba, and approaching in value to that of the English ash. It is very heavy, the heaviest of all West Australian kinds of timber.

EUCALYPTUS EXIMIA, from the slopes of the blue mountains in New South Wales, is known as the Mountain Bloodwood tree, and attains a maximum height of 80 feet. It is a stately and handsome tree, the abundant bunches of flowers being conspicuous among the dark foliage when in about October the tree bursts into blooming. It affords no durable timber, but good fuel, the wood being soft and light colored. The author here remarks that the lid of E. eximia affords excellent material for tracing the metamorphosis of a calyx into a corolla, and gives an excellent lesson on the subject.

EUCALYPTUS FOELSCHEANA, found in the vicinity of Port Darwin, on sandy soil, is a shrub, sometimes flowering at the height of 2 feet, the greatest height attained being 20 feet, with a stem diameter of only 12 inches as a maximum. The leaves are large, measuring often 4 to 5 inches in length and 2 to 4 inches in width, and exceptionally in young plants to 9 inches in length and 6 inches in width.

EUCALYPTUS HOWITTIANA, found by Dallachy near Rockingham Bay and other places, but nowhere gregarious. A tree attaining a height of 100 feet, and at the base a girth of 12 feet. It is one of the limited number of Eucalyptus species available for shade trees. The author here gives some *àpropos* remarks on the raising and transplanting of Eucalypts.

EUCALYPTUS PATENS—the Blackbutt of South-western Australia, is a tree attaining a height of 120 feet, the clear stem reaching sometimes 60 feet, with a diameter of 6 feet in its lower portion, and even 10 feet near the base. Its timber is considered durable in S. W. Australia; it is tough, hence used for wheelwright's work, and is difficult to split. A dissertation is here furnished on dry distillation for the separation of the tar, vinegar and spirits, in which it is stated that from 100 lb. air dried wood would be obtained nearly 2 gallons of vinegar of proof strength, affording by simple chemic processes pure acetic acid, or fit for entering into various dyes, or eligible for combination with many chemical bases, or answering after purification for preserving culinary fruits.

EUCALYPTUS SALMONOPHLOIA, from the upper eastern part of Swan River and its affluents. A tree attaining to fully 100 feet in height, known vernacularly as the "Salmon-colored Gum tree." As it is one of the oil-bearing Eucalypts, the opportunity is taken of discoursing on the qualities and uses of Eucalyptus oil, its effects on the blood and brain, and on animals, insects, &c. One-half per cent of the oil will destroy crayfishes in water.

EUCALYPTUS SALUBRIS, from the eastern bases of the Darling Ranges, towards the more arid inland tracts, as far as Victoria Springs (Giles), forming with E. salmonophloia small open forests. This is the "Fluted Gum tree," and also "Gimlet Gum tree" of the West Australian colonists, so called on account of the broad longitudinal often twisted impressions, or wide blunt longitudinal ridges of the stem, a characteristic quite unique. The specific name is from the sanitary importance of this tree which contains an extraordinary abundance of oil in its foliage, and which renders this species significant. A number of instances are given of the uses and effects of Eucalyptus oil; its antiseptic power has been proved by injecting it into the veins of rabbits, preventing thereby putrid decomposition and mummifying the cadaver. One-half per cent of oil in water will preserve raw meat from decay; one part and a half of oil in 1000 parts of fluids prevents the development of bacteria. Indeed, stagnant water into which many Eucalyptus leaves have dropped seems to prevent origination of fever even in malarial regions.

EUCALYPTUS TERETICORNIS, from Gippsland to New England. A good-sized tree when well developed, but seldom exceeding 100 feet in height. It is known as "Red Gum" and "Flooded Gum." The timber is pronounced excellent, and seems to participate in the durability and general qualities of that of E. rostrata. This and E. rostrata, and perhaps some other species, become sometimes destroyed over extensive areas by a Pasmatideous insect, which, when occasionally developing in vast numbers, devour the foliage of these trees so completely as to cause them to die off.

EUCALYPTUS TESSELARIS, from near the south-eastern shores of the Gulf of Carpentria to the vicinity of Moreton Bay. A tree generally of middle size, but tall in many places; leaves very long and narrow. Colonists designate this tree as the "Moreton Bay Ash." It extends to New Guinea. It must be regarded as a species of considerable importance. It is not only content with dry localities, whether ridges or flats, but braves even the long continued hot winds of the midsummer in Central Australia on places where the thermometer will give on unshaded spots to 154 degrees. Even contending against such climatic adversities, this tree will gain a height up to 150 feet and a stem diameter of 3 feet. The timber is easily worked, but not very durable when exposed to weather. Kino is exuded by this tree in not inconsiderable quantity periodically.

EUCALYPTUS TODTIANA, named in honor of Mr. Emil Todt, one of the artists engaged on the work, is a native of West Australia. It is a small tree, not perhaps of any technic importance, but will yield fuel in localities too arid for numerous other kinds of Eucalypts.—*Leader.*

COCHINEAL AND COCHINEAL COLOURING.

Cochineal is not a substance that can be said to be of any very great importance from a pharmaceutical point of view, but, owing to the many practical uses to which it is applied in the arts, no chemist can well afford to be ignorant of something regarding its history, its properties, and its derivatives. We intend giving a short account of these; and, for the purpose of giving the paper a practical application to pharmacy, we will touch upon various processes for making cochineal colouring, a most useful, but, if we may judge from the amount of correspondence it provokes, a most troublesome accessory to the pharmacist's stock-in-trade.

NATURAL HISTORY, &c.

The Coccidæ are a very numerous and very peculiar class of insects, which attach themselves to particular plants, on the juices of which they feed. The male Coccidæ are minute two-winged insects, the wings closing horizontally

over the body, while the abdomen is terminated by two long and fine filaments. The females, on the contrary, are wingless, almost limbless, and remain fixed to the spot on which they are placed or to which they attach themselves. Of this numerous family of insects, many of which are very troublesome and destructive, there are at least three distinct species which are of considerable commercial value, and which are, in consequence, more or less carefully protected or cultivated, namely, the *Coccus lacca*, the *Coccus ilicis*, and the *Coccus cacti*. The *Coccus lacca* is a native of Siam, Assam, Burmah, Bengal, and Malabar, and yields the various products known under the general name of "Lacs." The insects attach themselves to the branches of a tree, and propagate with such marvellous rapidity that they quickly cover the whole surface. During their short lifetime they secrete a resinous colouring matter, which is permanent, and, being constantly increased as generation after generation is propagated, soon forms solid masses of considerable thickness. These masses the natives collect and treat in various ways, and thus produce all the varieties of lacs known in commerce.

The *Coccus ilicis*, known as "Kermes," is abundant in various parts of the South of Europe, and also in India and Persia. The female insect burrows under the epidermis of the leaves or young shoots of the Kermes oak (*Quercus coccifera*), where it grows and swells, covering the leaves and branches with a series of excrescences, in which the eggs are deposited and where the insect finally dies. The kermes is gathered before the eggs are hatched, and produces a colouring principle which has been known and used from ages so remote that it is supposed to have been the substance used in dyeing the curtains of the Jewish tabernacle.

The third species, with which we have more immediately to do at present, namely, the *Coccus cacti*, has only been known in Europe from about the beginning of the sixteenth century. It was originally discovered in Mexico, and only of recent years has it been introduced and propagated in the Canary Islands, the island of Teneriffe and Algeria. It lives on the plants of the cactus family, and particularly on one, commonly designated the "Cochineal Plant," but known to the natives as the "Nopal" (*Opuntia cochinillifera*, or *Cactus opuntia*). The nopal plant is indigenous to Mexico, where it grows wild, but it is also largely cultivated, and the insects obtained from the two sources, namely, from the wild and cultivated plants, differ in their commercial value, that from the former being of inferior quality. This is called *Grana silvestres*, and is smaller than the *Grana fina* (cultivated), also called Mesteque, from the name of a province. At the proper season the natives take the young female insects, which have been carefully preserved on the stems of the cactus from a previous crop (the succulency of the plant permitting of their being kept for a considerable period), and placing them on the young plants they quickly grow and multiply. Three months is about the time allowed to elapse between the sowing, if it may be called so, of the insect and the gathering in of the new crop. At the proper season the insects are swept off the leaves of the nopal plant into convenient receptacles, when they are either killed by a momentary immersion in boiling water or by heating them in ovens, and less frequently still by exposure to the sun. According to the different modes of killing the insect is ascribed the appearance of the cochineal as brought to the market, those thrown into hot water and afterwards dried forming the dark (*negra*), while those placed in bags and heated in ovens constitute the silver (*blanco*).

CHEMICAL HISTORY, &C.

The colouring principle of cochineal was first separated in an impure state by Pelletier and Caventou, by treating the cochineal first with ether to extract the fatty matter, and afterwards digesting the residue in heated alcohol. Some idea of the colouring-power of cochineal may be gathered from the fact that thirty infusions with alcohol were required before it ceased to yield colour, and even then it was not exhausted, as was proved on adding other media to the digester. The percolates on cooling deposited a bright red granular mass, which on spontaneous evaporation assumed somewhat of a crystalline structure. The colouring principle thus obtained was considered by Pelletier to be an azotised compound, but Dr. Warren de la Rue, who subsequently investigated this colouring principle, found that it contained no nitrogen, and that it had the formula $C_{14}H_{14}O_8$. As this compound had distinct acid properties he gave it the name of "Carminic Acid," and this name has become very much synonymous with carmine, carmine of commerce when pure being simply carminic acid plus a small percentage of the precipitating agent, such as alumina, oxide of tin, or albumen. Carmine is prepared in a variety of ways, but the variation, it will be found, consists as much in the different precipitants used as in any distinct variation of the product itself.

An aqueous infusion, for example, is prepared, and bichloride of tin added, and the whole put into shallow vessels, when carmine slowly deposits on the sides of the vessels. Or cochineal is added to boiling water and allowed to infuse for a few minutes, when powdered alum is added, and the mixture again brought to the boiling-point, allowed to cool, filtered, and set aside to deposit. Or this process may be varied by adding, previous to the alum, a certain proportion of cream of tartar. Or the cochineal may be boiled with carbonate of potash, to which the alum is afterwards added. Carmine is insoluble in ether, is soluble without decomposition in sulphuric acid, hydrochloric acid, and ammonia, while chlorine, on the other hand, has a powerful decomposing influence upon it. An aqueous solution gives a beautiful crimson red with caustic alkalies, while oxymuriate of tin and cream of tartar or oxalate of potash give respectively a red and an orange red precipitate. An aqueous infusion of the cochineal, it may be well to remember, changes to a reddish yellow on the addition of tincture of galls or stronger acids, and to a deep violet with lime-water, while it is precipitated deep red by alum, bright red by ammonia, violet blue by neutral acetate of lead, and dark brown, changing to olive green, by ferric chloride.

ADULTERATIONS, &C.

From it expensive nature cochineal has always been subject to adulterations, and much ingenuity has often been expended in perpetrating frauds of this nature. One of the most common is to deprive the cochineal of part of its colour by immersing in water and afterwards drying it, when it is sold as the dark (*nigra*), or it is "doctored" with various substances and boldly sold as the silver (*blanco*), cochineal. To detect frauds of this kind, as well as to test the value of inferior cochineal generally, recourse is had to one of several methods of estimating its tinctorial power. The simplest plan probably is to exhaust a weighed portion of the sample with a given quantity of water, and compare with a standard sample by the help of a colorimeter. Another plan is to compare the colour imparted to wool with that yielded by a standard cochineal, this plan being the one generally adopted by dyers. Probably the better plan is to decolourise the infusion of a given quantity by a standardised solution of chlorine or chlorinated lime, or to precipitate the carmine with hydrate of alumina.

Dr. Crace-Calvert gives very good forms for estimating its dyeing-power on wool or flannel. The bath for scarlet tints is composed as follows:—Cochineal, 1 part; tin composition, 2 parts; cream of tartar, 2 parts; water, 1,250 parts. For the crimson bath:—Cochineal, 1 part; alum, 1·5 part; cream of tartar, ·75; water, 1,250 parts. The pieces dyed in these solutions are afterwards washed and dried, and, by a comparison of the relative shades, the value of the cochineal is determined. A considerable number of years ago a very systematic process of adulterating cochineal was discovered, whereby nearly 12 per cent of worthless matter was added to it. The fraud was apparently perpetrated something after the following manner:—The cochineal was first damped with thin mucilage, then shaken with sulphate of barium, and finally with ivory black, and dried. This gave it the appearance of dark cochineal, and the fraud seems to have been carried on for years. An exposure such as this is almost certain for a time to put a stop to the fraud from the very publicity which is given to it. There is, however, every reason to believe that such adulterations are still extensively carried on, and with an ingenuity so great that even good judges are often imposed upon. In addition to the adulterant already mentioned, carbonate, chloride, and sulphate of lead, oxide of manganese, oxide of iron, and other heavy substances are also frequently employed. To detect all such it should be kept in mind that the pure cochineal should not yield more than 5 per cent of ash, while after combustion the ash may be first weighed and afterwards estimated in the ordinary manner for non-organic compounds.

COCHINEAL COLOURING.

From what has already been said under the chemical history of cochineal, the rationale of the processes for preparing the majority of liquid colourings, so extensively used in confectionery and other operations, will be understood without difficulty. The colouring principle, as has already been shown, is soluble in water, but less so in alcohol—the stronger the alcohol the less capable is it of holding the carmine in solution. As, however, the alcohol is an expensive solvent, and as it presents no special advantages over the aqueous solution in the large majority of uses to which cochineal colouring is applied, it is seldom, if ever, resorted to in common use.

An aqueous infusion (prepared with heat) of about 1 part cochineal to 10 or 15 of water, and concentrated by evaporation to a proper degree, will answer for the majority of pharmaceutical preparations, such as Parrish's syrup, much better than any other colourings into which are introduced chemical compounds which often produce unexpected and generally vexatious complications. For most purposes, however, such a colouring is not bright enough, and recourse is, therefore, had to various means to produce a more brilliant preparation. Practically, by whatever means effected the resulting liquor is merely a solution of carmine, and the method employed to produce it will probably be determined more by the purposes for which the colouring is required, or by such considerations as convenience or expense, than from any great difference in the resulting product. Consequently, in making cochineal colouring we may either proceed to make it from the carmine direct, or we may make a soluble carmine from the cochineal itself. The former is accomplished generally by means of the solubility of carmine in ammonia, and all that is necessary is to digest the carmine in ammonia water sufficient to effect solution, diluting the resulting solution with water, and adding some preserving media, such as spirit or sugar, &c. An old form for a colouring of this kind, and one which gives as good results as can possibly be obtained working in this direction, is as follows:—

Carmine, pure, 1 oz.; solution of ammonia, 6 oz. or q.s.; macerate for a few days, with frequent agitation, and, when dissolved, heat gently so as to drive off excess of ammonia without reprecipitating the carmine. Dilute this solution with water, and add sugar, 1½ lb; rectified spirit, 4 oz.; water sufficient to make the whole measure 40 oz. The two main objections to all such colouring solutions are, first, the cost of production, it being quite apparent that the initiatory process of producing such a valuable pigment as carmine adds considerably to the expense of the finished product; and, second, the action that all acids have upon them in shortly reprecipitating the carmine.

Proceeding from the crude cochineal, no process is better known, or has been longer in use, than that of digesting with the aid of heat equal parts of cochineal, salt of tartar, alum, and cream of tartar with about eight parts of water. The process is so well known that we do not require to give it in full, but, inasmuch as complaints are not infrequent (and this not without cause, as we will immediately show) of difficulties in working the process, as well as in keeping the product, we may be excused for touching upon several details bearing upon these points. Alum, it is well known, is decomposed in presence of alkaline carbonates, the hydrate being thrown down with evolution of carbonic acid. When, therefore, a solution of cochineal is treated with salt of tartar and alum, the hydrate of alumina is liberated, and seizes upon the colouring matter, for which it has a powerful affinity, and would ultimately throw it down as an insoluble compound, known commercially as carmine lake, but which might chemically be described as impure aluminum carminate. On the addition, however, of the cream of tartar, brisk effervescence again takes place, with resolution of the colouring principle, so that the mixture now contains aluminum carminate in solution, plus certain salts, the products of decomposition. So much for the rationale of the process, without encumbering the explanation with too much chemistry. Now, if, instead of working with cochineal, we simply take equal parts of the three salts mentioned, and dissolve them in the proportion of water generally taken in this formula for cochineal colouring, we will find that the resulting liquid, after heating to drive off all carbonic acid, will be feeby alkaline, and, further, that it will be supersaturated with the resulting salts. Consequently, a slight excess of cream of tartar, a circumstance which might happen through carelessness in weighing, or a reduction in the quantity of salt of tartar through excess of moisture or other causes which might be mentioned, will materially affect the ultimate result so far as an alkaline or acid reaction is concerned. Not only so, but the liquid being supersaturated will necessarily begin to deposit on cooling, and will continue to deposit with decreasing temperature. The first observation here made applied to cochineal colouring affects the shade and depth of colour, &c., of the preparation, while the second observation affects its permanency, the precipitation from the supersaturated solution of necessity carrying very much of the colouring principle along with it. Behind this, however, a more important point still remains to be considered.

Like many other infusions of organic origin, the cochineal colouring will not keep without the addition of some agent to prevent putrefactive changes. Chloride of soda has been recommended for this purpose, but it is decidedly objectionable from a chemical point of view. Glycerine is also used; and, although we have had no experience of its anticeptic properties in this case, our experience in other directions analogous is that, unless added in considerable quantity, it will not arrest decomposition for any length of time. Sugar and alcohol are the agents more commonly employed, and in ordinary circumstances they are certainly the best adapted for the purpose; but here it is needless to point out that with a solution already saturated they encourage deposition, not only of the salts contained in solution, but of the colourising principle also. We have frequently seen, where these agents have been added, nearly one-half of the finished product lost from the sediment precipitated or thrown down. We only mention these points to give emphasis to the fact already sufficiently well known, namely, that the process is not by any means a perfect one, or without its difficulties in more than one direction. Mr. R. Rother (*Pharmacist and Chemist*, June 1880) tried to reduce the alum process to a scientific basis, and in a wonderfully-elaborate production gave a process which, divested of all its peculiarities of phraseology might shortly be explained as, first, the production of a pure aluminum carminate, and, second, the bringing of this carminate into an "available solution by means of a monad salt of a vegetable acid." The process is, shortly, as follows:—One part cochineal is macerated for two days with an eighth part (by measure) of hydrochloric acid, a fourth part of chloride of sodium, and four parts of water. Having occasionally stirred the mixture, it is ultimately decanted. The residue is then treated a second time in the same manner, and for the same length of time, with plain water, and a third time with the same quantity of water to which has been added one part chloride of sodium. The maro is then strongly pressed, and the several macerates mixed and allowed to stand until any sediment has subsided. To the clear liquid is added one-fourth part alum, and, when dissolved, one-third part solution of ammonia (16 per cent). The resulting precipitate is thoroughly washed with water, and finally dissolved in a solution of citrate of soda, made by dissolving one-eighth part citric acid in four parts water, and adding, with the aid of a gentle heat, subcarbonate of soda to saturation. The whole is made to measure three-and-a-half parts, and to this one-half part stronger alcohol is added "to obviate septic degeneration." The advantages claimed for this process are complete extraction of the colouring principle and a greater concentration of the finished product; the disadvantages, we may add, are the time and attention required in its preparation, the certainty of a loss of colouring matter by precipitation on the addition of the alcohol, and, like many other scientific formulæ, a product frequently uncertain and unsatisfactory. Quite unconscious that Mr. Rother had been working in the same direction, we had made a series of experiments with the view of effecting solution of the impure aluminum carminate of the old process by means of the most suitable vegetable acid. In doing this we found that citric acid was in every respect the best agent, and, in substituting a proper proportion of this acid for the cream of tartar of the old process, we found a product could be obtained at once permanent and satisfactory. We give the process, with some degree of confidence, as the simplest and best that has yet been given for cochineal colouring:—Finest silver-grain

cochineal, 1 oz.; subcarbonate of potash, 1 oz.; potash alum, 1 oz.; citric acid, ½ oz.; sugar, 4 oz.; water, quantity sufficient. Boil the cochineal bruised in a glass or copper vessel of suitable capacity in 8 oz. water, to which the subcarbonate of potash has been added. Mix loosely the potash alum and citric acid in powder, and add gradually to the boiling liquid, and continue to boil until effervescence has entirely ceased. While still hot filter on to the sugar, and wash the filter with hot water sufficient to make the whole measure 12 oz. This gives a beautiful and permanent crimson with a slightly alkaline reaction, but should a darker red be reqnirid the citric acid may be increased by one-third.—*Chemist and Druggist.*

Japanese Plum.—The curator of Rosalind Park at Sandhurst has succeeded in bringing to maturity a variety of the Japanese plum, a fruit which ripens in winter when most other fruits are out of season. The *Bendigo Advertiser* says that about two years ago Mr. Gadd obtained from Japan seven varieties of the Persimons or Japanese plum, four of which he planted in the nursery in the park. The trees have thriven remarkably well, and one of them, known as the Kurokome variety, is now bearing fruit. When ripe the plums are of a deep reddish orange color, smooth skin, in size and shape like an orange, with a most delicious flavor resembling the rock melon. One of the plums weighed nearly 12 oz., and measured over 11 inches in circumference. Similar trees have been plauted in the Melbourne public gardens, but they have not borne ripe fruit yet.—*Leader.*

Eucalyptus Globulus.—Considerable attention is again being directed to this plant as to whether or not it is sufficiently hardy to survive our winters. That it is not, was, I thought, clearly enough proved some half-a-dozen years ago, when nearly every specimen in the country was killed to the ground. In the *Gardeners' Chronicle* of May 31 the Eucalyptus is again brought under notice, and spoken of as being hardy and passing unscathed through a Cornish winter. This may be true, still its half-hardy nature and non-suitability for our climate generally is well known, and the fact established beyond a doubt. In some warm, well-sheltered, maritime situations in the south of England it may and does succeed, but further north it is in most cases quite a failure, and has long since been expelled from the Arboretum. There a number of these trees were planted out experimentally over the park, but although they did well for several years, and in many cases had attained a height of from 12 to 15 feet, yet during a severe winter, some five years ago they were killed to the ground —not even one tree being left. If I remember rightly the Eucalyptus met a similar fate in Ireland at the same time. —[Yes. See p. 678.]—*Gardeners' Chronicle.*

Worms in Flower-pots.—1. The presence of worms in pots is injurious, inasmuch as their casts are not discharged only on the surface but into the drainage, which is eventually closed thereby to the passage of water. Great care is therefore taken to get rid of them. 2. They do not exhaust the soil, but they destroy its mechanical condition. 3. We assume that the pots are standing on the ground, otherwise the worms must have been in the soil before potting. The ground within cold frames should always be surfaced with a thick layer of coal ashes or rather fine cinders well rammed together, so that no worm can pass through. If the soil were first moistened with tar-water, and left to dry for a day before laying the ashes, the efficiency of the protection would be decidely enhanced. In the case of small pots, which are not too heavy to be inverted on the hand, worms may usually be removed by that process; their casts may also be taken from the draining material. Where the ball is large worms may be brought to the surface by watering once with lime-water. The use of this must, however, be restricted to plants which do not object to lime in the soil. Fuchsias, pelargoniums, roses, cinerarias, calceolarias, primulas, myrtles, and their congeners are of this class. Heaths, and all other plants which naturally grow in peat, cannot withstand lime. Rhododendrons also object to it, and to azaleas it is injurious in only a slightly less degree. Before applying the lime remedy a passage should be secured through the drainage by probing it with a small stick through the hole in the bottom of the pot.—*Australasian.*

To Keep Milk Sweet.—Milk may be kept sweet for a short time by scalding, but that does not improve its flavour. By putting a teaspoonful of fine salt or horseradish in a pan of milk it may be kept sweet for several days. Milk can be kept a year or more as sweet as when taken from the cow by the following method:—Procure bottles, which must be perfectly clean, sweet and dry; draw the milk from the cow into the bottles, and as they are filled immediately cork them tight and fasten them with a string or wire; then spread a little straw in the bottom of the boiler, on which place the bottles with straw between them, until the boiler contains a sufficient quantity. Fill it up with cold water, and as soon as it begins to boil draw the fire and let the whole cool gradually. When quite cool, take out the bottles and pack them in sawdust in hampers and store away in the coolest part of the house.—*Leader.*

The Ginger Beer Plant.—There stands before me in an ordinary white glass bottle that fungoid phenomenon, the so-called Ginger Beer plant. I had heard much of this very curious thing of late, but till now had not seen it. An old neighbour, who is very enthusiastic about it, has brought me, however, the bottle that is before me, and its contents are water sweetened with sugar, some pieces of whole ginger, and the "plant"—which in bulk is perhaps enough to fill an ordinary teacup resembles most closely Tapioca as purchased from the grocers. It is white, in many pieces and form; and when handled is found to be fairly firm, somewhat slippery, and very light. Still its normal position seems to be at the bottom of the bottle, until, in the process of change which goes on within, the pieces ascend to the surface, and there remain for a time, and presently return to the bottom, so that whilst the contents are said to be working these Tapioca-like pieces of fungus are constantly ascending and descending. It is evident that carbonic acid gas is also being fast formed from the sugar, and this, too, is constantly ascending to the surface in small globules. Even portions of the ginger at times are affected with the motions going on, and ascend and descend as do the lighter and more buoyant fungus. This so-called plant certainly cannot be credited with the production of ginger beer. It simply produces an aërated liquid in this way, that the fungus seems to convert the sugar or saccharine into [alcohol and water, accompanied by the emission of] carbonic acid gas; and evidently as the pieces become charged with the gas they become buoyant and ascend, falling again when the buoyancy is lost. In twenty-four hours the sugar and water are converted into a pleasant subacid beverage, and either ginger or essence of lemon creates a non-effervescent drink far more pleasant than is ordinarily manufactured. Fresh water and sugar should be added about every twenty-four hours.—A.D.—*Gardeners' Chronicle.*

Climbing Palms.—The banks here begin to be most markedly festooned and trellised with a curious Calamus, or climbing Palm, the fronds of which are prolonged into a bare creeping stalk, furnished with curiously reversed hooks, so that once the frond falls against a branch it attaches itself securely by means of these recurved thorns, and thus climbs higher and higher, often fringing the top of the forest with graceful heads of swaying fronds, which with their waving whip-like terminations point straight skywards, as if seeking for greater heights to climb. The motto of this Palm should certainly be "Excelsior," and it might also be taken as a vegetable type of ambition. Beginning in the lowliest form, the young Palm looks like a broad-leaved Bamboo with divided leaves—suggesting strongly its poorer and simpler relations; it soon begins to aspire, and from being first a ground-growing shrub, it throws out a long flexible stem, rising far above the first humble set of fronds, and by means of its sharp hooks making use of every support in its way to climb higher and higher. Soon the leaves or fronds become more elegant. They split up from their previous bifid condition into many filaments, and at length the once lowly, feeble thing, by making use of everything that comes in its way and can give it a lift, looks proudly forth from the top of some giant tree, and for a while content with the attainments of its ambition, has time to pause and throw out its flowers, which turn to bunches of scarlet Dates. Its fruit has a thin, sweetish pulp around it, which seems harmless, at any rate to man, but I have never noticed any bird or beast devouring it. The colour of the leaves is a yellow-green, and it forms a decidedly bright addition to the river landscapes. "The River Congo," by H. H. Johnston, F.Z.S.—*Gardeners' Chronicle.*

THE ENEMIES OF TEA AND CACAO.

In a recent issue of the local "Times" appeared a letter signed P. F. L. upon "*Helopeltis Antonii* and Cocoa," to the personal tone of which even the editor of that paper took objection. Everyone who has ventured to give his opinion upon the cause of the disease now affecting the cacao is abused and sneered at, except Mr. T. N. Christie, and the reason why this gentleman is spared, is summed up in the following sentence:—"I am glad to observe that Mr. T. N. Christie has again shown himself to be a man of great parts and deep penetration : *I fully endorse his sentiments*." The italics are ours.

There is neither proof nor argument in the letter, but it abounds in such wild statements as this : "From what I can learn the *Helopeltis* is no other than the same identical fly that killed out most of the Cinchona in Java." Now we saw the effects of the scourge in Java, and though it no doubt threw back the cinchonas a good deal by depriving them of their leaves it never, that we saw or heard or read of, killed out a single tree. The case of tea is different, though here too we have never heard of it actually killing out the plants. But as the leaf is the part of the tea for which it is cultivated any injury to it means certain and irreparable loss, and it was pitiable to see in Java a fine tea-garden as bare as though swept by a blast of fire, the bushes having been pruned to within a few inches of the ground to get rid of the pests.

The would-be Daniel of the "Times," who says that "those who do believe in the fly will have a long laugh at Mr. Vollar and his colleagues," proceeds to ask him (Mr. V.) the following sapient question : "As regards drought, if that be one of the causes of this fell curse, perhaps Mr. Vollar will explain how it is that the tops of the trees die while the bottoms remain alive and keep sending out branches which are also attacked by the flies, &c." We suspect the laugh will be long and loud against P. F. L., who, living in the nineteenth century and professing to understand *something* of agriculture, evidently believes that a tree can die at the bottom and live at the top! The very first indication of root-disease is and naturally must be the withering of the topmost shoot of the tree, and the sending out of young shoots from the stem is the desperate effort of nature to recuperate itself. Another assertion by this writer which we are inclined to receive *cum grano salis* is that "notwithstanding their (the flies') antipathy to Mr. Jardine's Caracas trees, I know of one estate where their partiality for that species was so great they actually killed out the whole place." He follows this up with the gratuitous observation that "after reading his (Mr. Jardine's) conflicting harangue," I came to the conclusion that he knew nothing about the blight," Mr. Jardine being one of the most experienced, intelligent and observant of Ceylon planters.

But we have already wasted too much time and space over this self-sufficient scribbler. To turn to writers worthy of more serious regard we find that Mr. Moens in his "Cinchona Cultivation in Asia" mentions that "in 1868 Van Gorkom first discovered amongst the cinchona a disease, the cause of which could not be traced, but it was ascribed to the puncture of an insect. From that time the leaves were yearly attacked by this disease. It was sought to destroy it by sprinkling the leaves with all sorts of liquids, lime water, tobacco water, &c., but without avail. The cause also was sought for, but for a long time was not found. Now one thought it was an insect, then something else, till I, in 1875, discovered the worker of the mischief in the *Helopeltis Antonii*, upon whose habits of life more light was being thrown. The insect was first described as being harmful to tea by S. E. Peal, and shortly afterwards by Meyboom in Java. In Peal's work 'The Tea Bug of Assam' is found a very correct description of the formation of the insect and of the effects of its sting upon the tea-leaves. The appearances upon cinchona are perfectly analogous to them. The *Helopeltis Antonii* is in its full-grown state 11 millimeters [·43 of an inch] long. It is to be identified by the spine on the thorax which is formed like a knob. The female has a reddish brown, the male a black, thorax. The female lays from 12 to 14 eggs, which are transparent and white, 1½ millimeters [·06 of an inch] long, and with two threads attached to one side. These are laid in the bark of the young branches, in the petiole, or in the mid-rib of the leaf, after the female has made a puncture in it with its ovipositor. The threads project outwards. The young insect is very small, yellow-brown and without wings. It undergoes various metamorphoses before it finally assumes wings. These animals mostly reside on the underside of the leaves and occupy themselves most industriously. Young as well as old feed upon the sap of the leaves and young branches, which they assimilate through their proboscis, with which they penetrate the sap-vessels. The wounded part speedily turns brown and the growth is arrested; the unharmed portions grow on, but the end of the leaf assumes a curled or crumpled appearance. If the leaf is wounded in many places then it curls up into itself and at last turns black. A plantation that has been attacked is easily recognised by the dull, sickly look of the plants."

As will be seen from the letter of our correspondent "W. B. L." which we publish elsewhere, he looks upon the insect as the consequence, not the cause, of the disease. The facts stated by Mr. Moens must, however, be taken into consideration, that in Java *seven* years elapsed before the cause of the cinchona disease could be conclusively brought home to the *Helopeltis*. The fact seems to be that in certain countries, or on certain estates, or at certain seasons, according to the condition of the weather, we suspect, it carries on its destructive work silently and secretly, while on others, or at other times, its performances are plainly evident to eye and ear.

We conclude with an extract from the *Indian Tea Gazette* regarding the unusually severe ravages of a caterpillar upon tea in Assam :—

We have to acknowledge the receipt of a box containing specimens of a species of a caterpillar of a dark brownish color which has done a considerable amount of damage to a garden in the District of Mungledye, Assam.

This pest has devoured every leaf, both young and old, on all the bushes of about 75 acres, and off one bush alone 2 lb. of caterpillars were taken. The trees visited by this insect although *bare* as regards leaf, have not received any injury to their wood, and it is further noticed that as soon as the caterpillar turns into the chrysalis stage the bushes begin again to "flush." The Manager says that all hands are employed "picking" them off the bushes.

This blight is not unknown, having been referred to by Mr. S. E. Peal of Sapakati, Assam, in one of the many valuable Papers on the subject of *Tea Blight* contributed by him to the columns of this Journal.

SATISFACTORY TEA RESULTS IN CEYLON.

The Superintendent of Abbotsford, Lindula, Mr. A. M. Ferguson, jr., has handed us a tabulated statement of his experience in tea-making for the half-year ending June 30th; and as the figures are perfectly reliable and will be, we hope, exceedingly interesting and encouraging to all growers of this new product, we gladly publish them for the benefit of all those whom it may concern. He accompanies his information with the following remarks :—"You will see that I have made all my weeks end on a

Sunday: the reason of this is that the reports being made up every Monday, it is more convenient to add in the rainfall of the Sunday with the previous week. The total rainfall is 23·59, which analysed stands thus:—January ·61, February ·72, March 6·34, April 1 12, May 5·80, June 9 00, against the Langdale average for 8 years of January 3·67, February 2.09, March 2·34, April 7·01, May 6·57, June 17·55: total 39·23 So that the first six months of 1884 show a deficiency of 15·64 on the average. This drought suited the high estates, but proved for a time detrimental, we believe, to the low country ones. During the six months under review, 90 out of the 110 acres have been very carefully pruned, all the prunings being buried along with all surrounding rubbish. The pruned portion has not yet recovered itself, which accounts for the great falling-off latterly in made tea, but in spite of this the average yield for the whole acreage for the six months is 529 lb. per acre. The yield and average will now go on steadily rising till the end of the year, when I shall again, if spared send you the 12 months' returns, showing I hopeover 600 lb. per acre. We have had a slight, touch, of red spider and helopeltis, but nothing to peak of, as the figures prove."

Returns from 110 acres of tea, 7 and 8 years old, on Abbotsford Estate, 4,600 to 6,100 feet, for 6 months, January to June 1884:—

We have also received from a highly esteemed planting friend some tea statistics which he asks us to publish if we see fit. As all that concerns tea is of great value just now, especially when it has the guarantee of a good name at its back, we willingly make room for the following letter, but we must say we were at first startled by our friend's figures. Those standing opposite each month evidently represent the yield of *one* acre. In that case the yield for the twelve months would be 1,216 lb. per acre! A grand out-turn, but one which we by no means consider impossible: as witness Mr. Armstrong's 1,200 lb. off one particular field. Our correspondent writes from "Lower Dikoya":—

"We are having the finest S. W. monsoon I can remember since 1875, it being also a very mild one. At the end of that year I planted five acres of tea (hybrid Assam) which gave me in one month this year (March) over 200 lb. made tea per acre, the only month I kept a separate account of this field. However, the following is the detailed account of a field from 1st January to 30th June 1884, pruned in July last and now four years old, viz:—

January...	78	lb.
February..	88	,,
March ...	126	,,
April ...	88	,,
May ...	106	,,
June ...	127	,,
	608	lb. per acre

made tea in six months. This quantity might have been increased with a more favourable season. *The low prices realized for invoices of this tea* may be accounted for, not by the quantity so much as the fact that 60 per cent of the plucked leaf is *young* shoots off trees or *rather plants* not yet two years old, thus producing a *dull out-turn and thin liquor.*

OLIVE OIL.—In California the olives are first dried on trays with slat bottoms, tiers upon tiers of these being piled in a kiln over a furnace fire. Then they are ground between stone rollers, worked by huge wheels turned by horse power. The oil thus pressed out is poured into tanks or huge butts. Here it has to stand and settle three or four months. There are faucets at different levels in these butts, so as to draw off different layers of oil. After it has settled sufficiently it is filtered through six layers of cotton wadding, then through one of French paper, before it is bottled. It is then of a delicate straw color, with a slight greenish tint.—*Leader.*

THE "INDIAN FORESTER" for June has the following articles:—1. Articles, Correspondence, etc.—Sandal; the Sandal Wood Oil Stills of South Canara; a Point of Forest Law; Report on Cinchona Plantations in Madras; Weather Indicator from Bermuda; Forest Revenue Chalans; Revenue and Expenditure of the Forest Department; the Maipak. 2. Reviews.—Mr. Moir's Report on the "Chos" of Hushyarpur (1883); Madras Agricultural Essays. 3. Official Papers.—Report on Locusts; Instructions how to Preserve Plants Intended for Identification. 4. Timber Market.—Messrs. Mackenzie, Lyall & Co.'s Calcutta Timber Market Report for March and April. 5. Notes, Queries and Extracts.—The Cardamom Hills of Travancore; Rearing Silkworms in the Changa Manga Plantation; Guinea-grass and Lucerne; Rules for Soils; Cashaw; Common Forest Trees of the Adirondacks; matches. 6.—Extracts from Official Gazettes. We make an extract:—Madras Agricultural Essays.—The report of the Madras Agricultural Exhibition, a copy of which has been sent to us, contains in addition to the usual information as to exhibits, prizes, attendance, etc., the best of the essays submitted to the Committee by private competitors. Two essays are published on the management of soils under coffee in Southern India, four on the best and most economical methods of utilizing irrigation water, and two on the best method of laying down fuel plantations in India. The essays on coffee soils are interesting as far as they go, but they are more or less incomplete. Both authors insist strongly on the importance of good manure, and in Mr. Clarke's essay stress is very rightly laid on the fact that soils under coffee owe the diminution of their fertility far more to loss by waste than to the removal of a material in crop. The author points out that if the soil is to be kept in a fertile condition this loss by waste must be prevented, and he shows that such a process, although necessarily expensive, can with care be made profitable. He urges that organized experiments should be made to elucidate the best available methods by which this can be done,

and emphasies the necessity for rigid economy and scientific knowledge of coffee cultivation under its present conditions is to be carried out with profit. The essays on fuel plantations are of very general interest, and we particularly commend that submitted by Mr. Rhodes Morgan. It is obvious that fuel plantations if carefully conducted must of necessity be profitable, for the demand for fuel is probably everywhere on the increase, and a plantation when once fairly started is little liable to damage from excessive or insufficient rainfall. The best tree for fuel plantations is said to be the *Casuarina muricata*, which easily adapts itself to climatic variations, grows with great rapidity, and moreover yields timber capable of bearing a very high cross-strain. After securing a plot of suitable land near the market where the wood is to be sold and easily irrigable, casuarina plantations can be laid down by sowing the cones in shallow rows. The seedlings should be planted out when 9 inches high, and for 100 acres of land about 1½ lakhs of plants should be laid down in the nurseries. The seedlings should be well watered up to the time of transplantation, and after transplantation the watering should be continued until the young trees are in vigorous and steady growth. A seven year old casuarina tree averages 60 feet in height and 30 inches circumference near the ground. The price of seedlings is given at R6 per 1,000 and 1,200 or 1,500 to the acre should be allowed. Pitting the ground costs about R8 per acre, and watering about R26. Fencing, quit rent, and miscellaneous charges bring up the total cost per acre to R64. An eight year old tree contains on average 10 cubic feet of wood, and supposing 1,000 trees per acre to survive, 10,000 cubic feet of wood would be produced, the weight being 267 six-seventh tons. At R8 per ton this would realize R2,142-13-8. Interest charges, felling, sawing, carting and supervision bring up the total expenditure to R842-8-5 per acre, and the net profit is R1,300-5-3. Other good fuel trees are the *Acacia arabica*, the *Albizzia lebbeck*, which also produce good timber, and the list could be easily enlarged. It should be remembered that *Casuarina* grows best in light sandy soil, and if any part of a block of land intended for a fuel plantation should be found of stiff cotton or clay soil, some other species of tree should be laid down. In a fuel plantation the coppice system should be followed, *i.e.*, each portion of the block should be felled completely in rotation. The stools will shoot up freely and regularly, but the outturn will be slightly less than that of the first cutting. After three or four coppicings have been effected the land should be replanted with another species of tree, whenever this is possible. But on sandy soils the *Casuarina* is so far superior to other trees that it is better to let well alone, and not attempt to lay down new varieties. In hill climates such as that of the Nilgiri Hills, the best trees for fuel purposes are those imported from Australia, the Acacias *Melanoxylon* and *Dealbata*, and in particular the *Eucalyptus globulus*. Mr. Morgan states that were the many acres of grass land in the neighbourhood of Ootacamund planted with a mixture of these trees, they would afford an abundant and perpetual supply of fuel more than sufficient to meet all possible requirements. A fuel plantation in the Nilgiris laid down with wattle trees would be fit for felling in seven years, and would produce a net profit of R664 per acre, the price of fuel being calculated at R8 per ton. A plantation of *Eucalyptus globulus* would probably stand five or six septennial fellings without diminution of outturn, and might even last longer than this. Decennial fellings would be more profitable, the net grain per acre on such coppicing being given by Mr. Morgan at R2,013. In the case of a 500-acre block of mixed natural jungle worked carefully and within easy reach of the fuel market, the net profit for 12½ years is estimated at R3,03,800, being at rate of R607 per acre. The exact amount of calorific power of any given tree is difficult of calculation, but may be said to increase with density and hardness of the wood. Resineous and oily woods are of little value as fuel, but most hard woods burn with a clear fine flame, and produce excellent charcoal, which may profitably be manufactured in fuel plantations. Mr. Morgan's interesting essay closes with some practical remarks on the enemies and diseases to which plantations are exposed, and the best means for their extermination.

"THE COCOA KING."

[FROM OUR ROVING CORRESPONDENT.]

[Our readers will peruse with interest the following account, which we take from the *Sydney Mail*, of Cadbury's Cacao or Chocolate factory, near Birmiogham, one of those well-conducted establishments which constitute so much of the glory as well as the wealth of Britain.—ED.]

I started off early for Birmingham proper—or improper, as the case might be—to make my tour of Messrs. Cadbury's premises. Proceeding by a suburban branch of the comfortable Midland line some three or four miles away from the heart of the town, I found myself on alighting from the train at a little wayside station, situated in a charming little valley which might have served for Rip Van Winkle's "sleepy hollow" but for the hive of industry it contained, and the strong, permeating, ever present and pleasant odour, as of freshly poured out chocolate, such as strikes the olfactory senses on entering a Spanish or Italian café abroad. On either side were gently undulating hills watered by a tiny streamlet that meandered in and out between the ridges, and trim meadows on which horses and cattle were grazing, farmhouses peeping out here and there amidst the hedgerows and copses in the most rustic fashion, as if "far from the din of cities and busy haunts of men;" whilst a colony of rooks, who were holding a caucus in thorough Birmingham style in a neighbouring group of elms, and explaining by vociferous caws the justice of their cause, lent a peaceful air to the scene, which even the one great colossal chimney of the factory in the dell below on the banks of the Bourn, did not altogether banish. This latter little rippling rivulet added much to the attractiveness of the locality, besides giving the place its name *more Americano*, and is said to be regarded by those disciples of Izaak Walton living in the vicinity with much veneration, many trout of respectable dimensions having been caught in its waters to gladden the hearts of the enthusiastic anglers, some of whom sally out after work-hours in the factory to indulge in their fondly-loved pastime of piscicapture. While on this theme, I could not help but notice the evident desire displayed by the firm to contribute in ways many and various, which can scarcely be recorded here, to the comfort, happiness, health, and well-being of the fortunate work-people who have the luck to be employed by them; the entire little community, numbering over six hundred souls, being bound together by the kindly influences of temperance, religion, and thoughtful watchfulness, by ties dearer and closer than the mere common bond between employees and capitalists of a stipulated service being given for a stipulated wage, as is the case in more mercenary establishments of the present day. Here the love of God and the love of man are welded together; and while the heads of the firm, with a judicious sensitiveness which can be readily appreciated, refrain from exercising anything like undue control over their workpeople, they show practically by deeds, and not by words, how much they have their welfare at heart, both here and hereafter. A cricket and football ground is provided for the men; and for the young women and girls a spacious playground fitted with swings and other contrivances contributory to outdoor enjoyment. These privileges are thoroughly appreciated; and the joyous indications of innocent pleasure that emanate from "haunts of leisure," in paraphrastic phrase, "between times," were refreshing to the ears of a sojourner in cities like myself, for it was delightful to hear the cheery shouts of the men at play, the merry laughter of the girls. But more substantial provision has been made by the firm for the comfort and convenience of their best workmen. On ground contiguous to the factory, and bordering on the road which runs on the southern side of the works, adjacent to the rook colony holding their caucus just mentioned, the firm have built 16 semi-detached villa residences, which are inhabited by their foremen of departments and leading hands—workmen who have shown by their general demeanour and assiduity in business that they are worthy of the consideration their employers have exhibited on their behalf. These villas are model residences, let at comparatively small rental; they are well built of brick in two colours,

fitted internally with taste; and each would easily bring a rental of £40 per annum in the suburbs of Portsmouth, although the inhabitants of these residences pay 5s per week for occupying them! To each house, moreover, is apportioned a front and back garden, and the tenants are enabled to grow their own vegetables and fruit, and decorate the front parterres with flowers. At the rear of every dwelling is an outhouse with appliances for washing, and a pump of good water, while the kitchens are fitted with modern cooking ranges. Behind these residences is a spacious orchard, planted with apple, plum, pear, and cherry trees; and at their extreme rear, to complete my description, flows the "Bourn," which at this juncture forms a natural cascade in miniature. Thus it will be perceived that Bournville is by no means lacking in attractiveness to those who admire the country. Of course, it being at the time of my visit as near an approximation to winter as the clerk of the weather could manage, now that he has mixed up the seasons and given us mild Decembers and terrible Mays, I was not in a position to fully appreciate the beauties of the place; but from its idealic situation I can well imagine what it must be in summer, especially in the halcyon month of June, when the roses bloom in the workmen's gardens and the rooks' nests in the trees are hidden by a sheltering green.

The nearest house to the factory is a superior villa residence, which the firm built especially for their energetic foreman. This villa is detached, and is a commanding and handsome dwelling, designed and constructed with evident taste and elegance of design. The grounds attached are spacious, and few more desirable homes are to be found. I must not omit to add that the all-important sanitary arrangements of these villas have been very carefully considered; and, before leaving this part of my subject, should mention that while the workpeople are at their several tasks—which are performed, by the way, on the system of piecework, which is most just alike to employer and employed—ample provision is made for the wants of their "inner man," and arrangements carried out effectively, so that they may have their meals comfortably. Spacious dining-rooms have been provided separately on the premises for both men and women. Gas stoves and cooking apparatus have been erected here, and hot dinners can be procured in a very few minutes. So complete are the cuisine arrangements that there is really no delay. In the females' cooking department a gas oven has been fitted, on which about 220 dinners are cooked daily. In addition to this an apparatus for frying, together with the necessary pans, has been provided by the firm for cooking chops and steaks, and such like. To demonstrate that there is no time lost in waiting, I may mention that about 60 chops can be cooked in about ten minutes. Many of the hands who bring their food ready dressed, of course, only require to warm it: but for those who wish to use the gas-oven or other apparatus there is ample accommodation, and no confusion occurs. Throughout the entire range of buildings order and regularity are preserved with scrupulous exactitude, particular attention—as might have been expected, considering the nature of the article manipulated—being paid to cleanliness. In this latter respect a commendable care is apparent, as I noticed that all the women and girls employed, and who outnumbered the men considerably, the taskwork being mostly suited to feminine hands on account of their greater delicacy of touch, were uniformly dressed in a brown holland costume, tightly fitting in at the neck and extending down to the heels, and which, by being tied in round the middle by a band of the same material, very much resembled a light ulster of the present mode, such a favourite with Landport young ladies! This costume of the workgirls, covering their whole dress as it does, make them look very neat and clean; and, as they are marshalled to enter the refectory, they appear as a little army of Amazons clad in Indian *khaki*, such as was adopted by our troops in the recent, and what very much looks like a present, Egyptian campaign. The firm, while looking after these points of detail in the dress of their employees, are evidently opposed, and very rightly too, to long working hours, especially where females are concerned. The women commence work at 9 o'clock and leave at 6, long intervals being allowed in between these ours for meals and the necessary rest required after wards. Every morning, too, from a quarter-past 9 o'clock to the half hour the "hands" assemble in the general dining hall for a short and simple religious service, so as to begin their day's work with the divine blessing. It has been remarked that this daily gathering helps to form a bond of union between the workpeople themselves, as well as between the employers and the employed. One of the firm, I was told, gives a short prayer and then reads a portion of scripture, and after a hymn has been sung the brief service is over, and work is resumed.

But I must hurry on to describe the manufacture of crude cocoa into the luxurious beverage which we relish so much at breakfast, or else my description of Messrs. Cadbury's works will be something like Shakspeare's play of "Hamlet" with the part of the young Prince of Denmark left out.

The cocoa plant, I may say at the start, is no stranger to me. I was not familiar with it at its first discovery, certainly, for that dates back to the period when Columbus originally found out the new Western World with all its wonders, although it must have been known to the Mexicans of Montezuma for centuries before; but I may undoubtedly state that I was on terms of acquaintanceship with the plant in its native wilds, even in the earliest days of my boyhood, for I went out to the West Indies when quite a child, and almost the most vivid impression I have of tropical vegetation is of seeing the bright green leaves of the cocoa tree, with its elliptical, oval-pointed, yellowish-purple fruit—something like a vegetable marrow of a somewhat peculiar shape. Each of the cocoa fruit pods contains some 20 to 40 seeds or "beans," which are imbedded in a sort of creamy, thick, acid pulp. Common enough in the West Indian islands of the Leeward group that stud the heel of the Carribbian Sea—such as Grenada, Trinidad, St. Vincent, and Cariacua—where the mountainous nature of the ground gives it that shelter which it requires as much as the heat for ripening. It is also to be found in Nicaragua, Honduras, Central America, Brazil and Demerara, and also, too, in the Mauritius and the unfortunate island of Madagascar which the French are now trying to find some pretext for annexing. I must point out here that shade is so absolutely necessary for the proper fruition of the cocoa, as well as a tropical heat, that the plants are invariably set beneath the shelter of a larger tree, which the Spaniards term *La Madre del Cocoa*, or "The Cocoa Mother;" and thus, in quiet groves as shaded and still, but for the parrots' chatter and the monkeys' gambols, as any that Virgil murmured the *Tityre tu patulæ* under the pods grow and the cocoa arrives at maturity. When the fruit is quite ripe it is gathered, generally by being sliced from the boughs by a cutlass wielded by the arm of some stalwart negro; the pod being slit open and the nuts with their creamy adjunct which holds them all together placed in casks, where they are pressed down by weights and left to ferment, so as to get rid of the pulp, and, as it is said, improve the flavour of the cocoa. After some little time has elapsed the nuts are then placed in wide open trays in the Boucan or drying-house —whence the name "bucaneer" originated, from those freebooters of the sea living on jerked or sun-dried meat where it is exposed for some days to the sun, after which the nibs are placed in bags and exported to England and elsewhere. On their arrival at the Bournville factory, the nuts of the cocoa—not coconuts, let the reader please remember—are transferred from the bags in which they are imported to large and capacious bins — not Binns, our national executioner previously alluded to as living in Birmingham when off active duty! From these bins the first process the cocoa undergoes is to cleanse it from all impurities of dust, dirt, and such like that accompanied it from the land of its birth. This is done by sifting it in a long cylinder fitted with variously graduated sieves. From these the nuts drop, automatically assorted to several sizes, into boxes below, cleansed from all superfluous substances, and ready for "cooking" —their second experience being to be roasted in revolving cylinders over bright coke fires. This is a very delicate process, and so important a one that very careful attention is necessary, and experienced workmen, whose judgment is almost unerring, are entrusted to superintend the ordeal. It is requisite for those who have charge of

the cuisine to determine the precise period at which the nuts are sufficiently roasted, for very much depends upon this point. A miscalculation in time, of course, would tend to spoil the flavour of the nibs, not to speak of burning them and so ruin them altogether; but it was satisfactory for me to learn from the foreman that mishaps rarely happen, for so practised are the hands responsible for the roasting that the work is, as a rule, admirably done. and the flavour of the nut invariably preserved. In connection with this process methods of treatment peculiar to the establishment are successively adopted. After being roasted the nuts are placed in trays of considerable superficial dimensions to cool. The fresh air speedily reduces the temperature of the cocoa beans, and they are then ready to be what is technically termed "broken down." The now crisp, roasted nuts are placed in a hopper, and afterwards raised by an elevator and passed through a machine which gently cracks them, disengaging the hard thin skin, which by this means can be separated from the nutritive portion of the nut—that is, the rich, glossy kernel known in the market as "cocoa nibs." The separation is effected by a winnowing machine. From the outlet of the cracking-machine the husk and nut are carried to a point over the "winnower," and as the cracked nut falls into its allotted receptacle below a powerful blast of cold air from the lungs of this machine blows away the shelly parts into an upper division of the same receptacle.

Touching these shelly particles, I have an "exshellent" joke to make, for I may mention confidentially, *en passant*, that I think I have discovered the nucleus of a secret which will probably be considered by Mr. Parnell and the Home Rule party as another grievance sustained by the natives of the Emerald Isle at the hands of their perfidious Saxon oppressors. I was told in the strictest secrecy that the cocoa husks are shipped to Ireland, where they are "used as a light but by no means unpalatable decoction, like weak tea, and sold under the designation of 'miserable'"—save the mark! What will Mr. Parnell say to this?

To proceed, however, with my description. After the nuts are broken and winnowed they are next taken to the grinding room, where a series of revolving mill-stones speedily resolve them into a thick brown fluid. From this liquid paste the oil is extracted—and there is some 50 per cent of vegetable fat in the nuts—by means of a certain process, a specialite of the firm which it would be injudicious to reveal; and then the substance, without the admixture of a single foreign element, but pure as it came originally from the tree, with the exception of being deprived of its fat, having "done Banting," so to speak, is known as "Cadbury's Cocoa Essence," celebrated for its purity and nourishing properties all the world over, an essence which indeed has gained "The Cocoa King" his title, and the little town on the banks of the Bourn its local habitation and name. The cocoa essence having been reduced to a very fine powder, not all unlike a detonating composition known as fulminite, is then weighed and packed automatically in the well-known packages familiar to all cocoa consumers, by an ingenious American machine which contrives to measure and put up some 20,000 parcels of this theobromine—or "food of the gods," as Linnæus christened it—per diem. The vegetable fat or "cocoa butter," as it is technically termed, extracted from crushed nib, is sold in large quantities to the wholesale chemists, by whom it is so "transmogrified" that it enters into a dozen uses which one would never suspect. Joking aside, however, cocoa fat has valuable healing and soothing properties that render it invaluable as an ointment, as which it indeed is in great vogue in the West Indies, and on the Spanish Main, as I well recollect.

The next article of Messrs. Cadbury's manufacture, and one almost as important as that of their cocoa essence, is the Mexican and other sweet chocolate for bonbonnieres and other dainty uses too numerous to be specified. The pure cocoa is in the first place incorporated with the best white sugar in a machine called a melanguer or mixer, where heavy granite rollers like millstones set on end, and a double-bladed knife acting as a screw propeller, thoroughly incorporate the substances into each other, after which it is flavoured with vanilla. The "Chocolate," as the material is now called, is then run into moulds, and cooled on stone slabs in a cellar, whose temperature more approaches to the freezing point than any other part of the establishment I visited.

After seeing chocolate thus "put through its faces," in slang phrase, I was ushered into the cream moulding room, where bonbons are manufactured apparently in quantities enough to fill all the bonbonnieres of the juvenile world. The place seemed, really, more like a mill—that is, a flour-mill—than a chocolate turn-out, for everything here—the floor, the ceiling, and all surroundings—was covered with a white efflorescent deposit, while pulverized particles of similar substance permeated the very air and every nook and cranny in the place. As for the girls working here, they were like so many pretty little mill-princesses, and seemed to perform their task of manufacturing those delicious chocolate creams, which some of us with a sweet tooth wot of, with a skilful expertness which constant practice in filling the tiny moulds could only teach. They manage to fill each mould with just sufficient of the cream and no more, thereby preventing waste of time if not of materials. Hardly is this done than the "creams" solidify, and when cooled they are taken to another department and coated with chocolate, whereupon all that has to be done is to eat them!

To turn to another industry in full work in this manufactory, and one almost rivalling the production of the cocoa essence, chocolato, and bonbons, one must imagine a change of avocation, and go in for carpentering, paper-hanging, and tinsmithery.

Of course thousands upon thousands—nay, millions, of millboard boxes to contain cocoa essence, in addition to fancy cardboard boxes and other dainty devices fer holding the various chocolate confections, have to be made in the year, and much ingenuity is displayed in their manufacture; the demand being so enormous for their cocoa essence that the firm had to employ elaborately constructed machinery to suit the requirements, one handy aid to labour cutting the card into the required shape, while a carefully devised appliance, not unlike an envelop-folding machine, glues the parts together and perfects the packet shell, the "output" of these two silent mechanical workers being some 12,000 each daily. Other machines are also employed to make the tin boxes for the outer casing of the essence, one especially cutting out the box-shape from the sheet tin, forming the top and bottom, bending the sides together, and stamping the whole into a complete form, without any solder or other annealing substance, in the most wonderful way. Of all the departments of the factory, the girls' "general room," where the various arts of box-making, fitting and packing were principally carried on, seemed to be the busiest; but perhaps this was from the fact of so many being grouped together in it, the apartment being at least two hundred and fifty feet long by sixty in breadth. Some hundreds of girls were here engaged folding, gumming, labelling, and otherwise constructing the fancy boxes to contain the chocolate and chocolate creams, whose manipulation and mode of manufacture have been thoroughly described; and it appeared really that the firm think it necessary that not only must the sense of taste be gratified by the manufacture of toothsome compounds, but the eye must be pleased as well; for many, indeed most, of the varieties of fancy boxes made in this room were admirable examples of art workmanship, the designs and pictures on some of the best being beyond praise; while in the vast assortment of decorative embellishment the most *exigeant* taste could not fail to be gratified. Cutting out paper and cardboard, filling, folding, glueing, packing, and stamping together, the busy girls get through their work *a merveille* and when they had perfected and turned out some little *chef d' œuvre*, it was beautiful to notice its finish and completeness.

I may state, in now concluding this brief account of my peregrinations round this interesting factory, that most certainly Bournville is one of the wonders of Birmingham, and my friend, I think, made no error and committed no *lapsus linguæ* when he styled Mr. Cadbury "The Cocoa King."

LICE IN HENS' NESTS.—Sprinkle the nest with a solution of carbolic acid. Bare soil is better than any material for nests. It is said that if a groove is made in a hen roost and filled with a mixture of lard and sulphur, the fowls will not be troubled with lice.—*Leader.*

"TEA STATISTICS IN EXCELCIS."

Such is the heading under which the local "Times" embodies our figures of the tea yield on Abbotsford, not in order to inform the few, who *do* read his sheet and who do *not* see the *Observer*, of the satisfactory progress that is being made in tea cultivation, but in order that he may devote half a column of editorial wisdom to the exposure of the "misapplied," "erroneous," "absurd," "comic" deductions which were made from them.

Now in our article it will be seen that we made no deductions editorially: we simply gave our correspondent's figures and remarks as he supplied them. But none the less do we consider that his figures *and deductions* are perfectly correct, and we feel sure that they will be accepted as such by all who study them. In order, however, that our Indian friends may not be led away by the specious arguments of the "Times" editor, whose chief object seems to be to encourage them in their belief that Ceylon planters tinge all their doings with a golden hue, which cannot be supported by facts, we take the trouble to explain our correspondent's figures, if such a term be applicable to what ought to need no explanation.

The totals of our correspondent's statistics stand thus:—110 acres have given 29,117 lb. of made tea in 6 months, upon which he remarks:—"The average yield for the whole acreage for the six months is 529 lb. per acre. The yield and average will now go on steadily rising till the end of the year, when I shall again, if spared, send you the 12 months' returns, showing I hope, over 600 lb. per acre." Upon this the "Times" observes:—"We cannot reframe therefore from pointing out that 29,117 lb. of made tea off 110 acres for six months is about 264½ lb. an acre. Our contemporary's informant thinks otherwise, however, for he makes the result exactly double, namely, 529 lb. per acre. This he has arrived at by *halving the acreage* [We italicize—ED.] and dividing the amount of made tea by it—a perfectly legitimate proceeding to show the probable yield for the whole year, if the second half-year was likely to produce as much as the first, which it is not. But he has forgotten that he has done this and calmly takes the result to be, not the probable result of 12 months' plucking, but the actual result of the past six! * * If 529 lb. are gathered per acre in six months, we should have thought that more than 600 lb. would be obtained at the end of the year, particularly if 'the yield and average went on rising.'"

Will our readers kindly study the logic of this tirade. Imagine a critic of figures supposing that our correspondent would, in order to arrive at the year's average, *halve the acreage and divide the amount of made tea by it!* Does it not strike him that the more usual way is to *double the yield* and divide it by the *whole acreage*?

Again, the superintendent of Abbotsford does not say that the *actual* yield for 6 months was 529 lb. per acre, but the *average* yield, a very different thing. As we do not believe in the value of tea-sales averages unless they represent an equal standard of tea, or the whole produce of every estate, so we do not believe in the practical value of the yield of a single acre or a single month, though the figures may be and are highly interesting. The great value of statistics is to show what the whole acreage of an estate has done, or is *reasonably* likely to do, for the whole year. For instance, we find that in the 8th week for 1884, Abbotsford gave 3,000 lb. made tea: this is at the average rate of 1,418 lb. per acre, and yet we see the average put down at 681 lb.: plainly showing that the total lb. made up to date were divided by 8 (weeks) and multiplied by 52 (weeks), in order to discover the true yearly average. The "Times" editor not only does not believe, but plainly denies that for the second half of the year Abbotsford will yield as much as the first. Now to show that it may be *reasonably* expected to yield more, we here re-state some of the facts we have already given. During the first half year, 95 out of 110 acres were pruned, 5 in February, and 90 in March, April and May, so that from July onwards all, even the latest pruned portion, will be coming into bearing, and will naturally be yielding more and more each month, while the trees themselves will be growing older and stronger, and presenting an ever widening plucking surface. Of course, our readers understand that all these and like calculations are based upon the condition that no disease do materially injure the trees. Another reason for expecting an increase of yield is that throughout the whole 95 acres, the prunings, weeds and near-lying rubbish, such as rotting-wood, ravine-soil, stable and cattle-manure, &c., have been buried in the rows on the upper side of the bushes, and surely this fact of itself would be quite sufficient for the manager of an estate to rely upon in looking for larger returns. The Calcutta Commissioner, however, may be a believer in the idiotic theory put forward the other day that it is useless manuring tea, as it sends its tap-root so far down into the subsoil!

MR. JARDINE ON CACAO AND ITS ENEMIES.

Mr. Jardine has thought it worth his while to answer the flippant letter in the "Times" which we recently noticed, and gives valuable facts as the result of his observation. He evidently believes that true Caracas cacao will resist the attacks of insects. We quote as follows:—

I have always held that the mischief done to the cacao shoots was due to an insect or insects; at the same time I think it quite possible that the abnormal season has had something to do with its unusual virulency. Surely I need not tell "P. F. L." that debilitated trees (equally with animals) are more liable to attacks of disease than healthy ones. What then more likely than that the sap was in some way changed, and rendered more palatable to the insects? It is a pity, no doubt, but still it is a fact, that I cannot attribute the damage done here to the *Helopeltis*, though I am bound to believe your correspondent when he states that the mischief done to places under his observation is due to them. I have not known the insect for so long as "P. F. L.," still I know it well enough, and deplore the damage it does to the cacao pods. When it is proved to me that the *Helopeltis* does not breed in the cacao tree, but in some other, and the attacks are all made by the *full-grown fly only*, I may then be prepared to believe the mischief is due to them; but, so long as I see the insect in its unfledged state in numbers, on the cacao pods, and *still see no harm done to the young shoots*, I hope I may be permitted to doubt. *Helopeltis* has been here for three years and caused much damage to pods, but is it not, to say the least, strange that during all that time they never attacked the young shoots? Most cacao planters will, I am sure, bear me out in this, namely, that for some years, *Helopeltis* has been numerous, and done more or less damage to cacao pods, but not to young shoots! In the face of "P. F. L's" sneering disbelief at my statement, that the destruction here was caused in a few nights, I repeat the assertion. From the time the insects disappeared from the 20-acre field I allude to—and be it observed that no other part of the estate was attacked—in about August 1881, up to the first week in May 1884, there had not been any sign of insect attacks on the place. I have had many opportunities of contrasting cacao grown under forest shade and in the open, and where shelter belts have been planted, and the opinion I have formed is that shade is hurtful, but shelter belts beneficial. These last should not be planted too close, say a chain apart, on sloping land, and 90 feet in flats. They may

he planted in a row as close as will cause them to meet in from three to four years, and where wind is suspected they should be grown checker-board fashion. "Too much capital is tried to be made out of the cry of 'poor land.'" All I can concede under this head is that cacao should not be planted on land where there is a hard, impenetrable subsoil. All ordinary soils will, I believe, grow it profitably. Why will people go out of their way to have a fling—perhaps thoughtlessly—at a neighbouring district? I see, in an extract you make from a correspondent's letter, he says his cacaos have no disease. Now, why not stop here instead of proceeding to say "and hear that it is only bad at Polgahawela. Cacao should never have been planted there, as the soil is very hard, and the climate hot and dry." Surely this is gratuitous opinion and advice, at the same time that it is much overdrawn. True, the soil in Polgahawela is hard *in dry weather*—and where is it not?—but the bulk of it is, in my opinion quite suited to grow cacao; it *is* hot, and so are most places where cacao is grown. As to its being dry, well, if an average rainfall of 90 inches in the year, well distributed over 10 months (January and February having usually only one or two showers) is dry, then it is dry; but I think most people would consider it wet. As it is a matter of great importance to all intending cacao-growers, I must ask "P. F. L." to tell me where the Caracas seed was got from which the trees killed by *Helopeltis* were raised. On receipt of this information, I may have something of interest to communicate.

THE CLIMATE OF UVA AND ITS SUITABILITY FOR TEA.

By the courtesy of the acting Surveyor-General, we are now able to place before our readers a table of rainfall averages at a considerable number of stations in Uva, for the months as well as the year, and showing the number of days on which more or less rain fell. The results fully bear out our contention that Uva has a climate favourable for the growth of tea, and eminently suitable for the preparation of the leaf. In many parts of Assam where excellent returns are obtained, the rainfall does not exceed 70 inches, while the distribution over the months is by no means so favourable as in Uva. No doubt the climate of Uva was and is eminently favourable to the production of coffee, much of which still holds its own, and is likely to do so, in the face of the fungus pest. But the conditions of rainfall for coffee and tea are much the same: an annual fall of 70 to 100 inches well distributed. We have not the slightest hesitation, therefore, in committing ourselves to the prediction that Uva will yet be as famous for its tea as it has been for its coffee. Sir Arthur Gordon can judge for himself from what he sees and hears on the occasion of his approaching visit, and, meantime, the figures for rainfall, added to actual experiments, more or less advanced constitute evidence not to be denied. Long may coffee preserve its pre-eminence; but, whatever happens to the Old King, certain it is, to use Sir William Gregory's words, that "Uva has not come to the end of her tether." The average annual rainfall of the nine stations where observations have been recorded is 89·37 inches (very little short of 90), the lowest figures being 74·67 against Badulla and 74·24 opposite Oodawera, while the highest, 109·86 inches (nearly 110 inches), are opposite Madulsima. From Badulla to Meeriabedde in Haputale, therefore, on the one side, and to Madulsima on the other, the rainfall is ample. At Badulla alone are the rainy days in a year fewer than 100; at the other eight stations, the number of days on which rain falls varies from 134 to 195, the average being close on 150. If our readers will glance at the table, they will observe that there is not a single month represented as absolutely rainless. The lowest number of rainy days in any month is 3; the lowest measurement in any month is 1·23 inch in June. The opposite extreme is 24 rainy days in November and 21·36 inches in December. The seasons differ from those on the western side of the Nuwara Eliya range, the bulk of the rain falling in the north-east monsoon, so that the pruning time may probably be different on the two sides, and labour for the purpose can be shifted from the one to the other.

To sum up, we repeat emphatically, that while many parts of Uva are suitable for cacao culture, the climate of the whole region is eminently favourable to the luxuriant growth of tea, and perfect for withering the leaf and preparing it for the market. The railway trucks on the line from Uva will yet be laden with tiers of tea-boxes, while lead, rice and other goods will be carried up in proportion.

G. H. SYMONDS,
Acting Surveyor-General.

Colombo, 11th July 1884.

GUTTA-PERCHA-YIELDING TREES.

Heer W. Burck, Assistant Director of the Buitenzorg Botanic Gardens, Java, has written, as an Appendix to the Report on these Gardens for 1882, a most elaborate memoir, embracing all that is at present known of the apparently large number and great variety of the trees which produce the gum called gutta-percha The gum varies in quality as the trees do in species (some of them appear to be figs), and the soil and conditions suitable for the growth of gutta-yielding trees vary, as in the case of india-rubber trees, from clay, loam and sand to swamp. We have had the article translated, and, did we think that any Ceylon planter was likely, after the experience with indiarubber, to take up the cultivation of the gutta-percha trees, we should have published the translation in the *Observer*. But we agree with Dr. Trimen, that, even more than in the case of the rubber trees, those which yield gutta-percha should receive attention from the Governments of tropical countries through their forest departments. We, therefore, restrict the translation of Heer Burck's very elaborate and lengthy paper to the columns of the *Tropical Agriculturist*. We believe there are some of the gutta-percha-yielding trees in the forests of Ceylon, and others of the species proved to be most valuable can be introduced; but it is in the vast forests of Borneo, Java and the islands of the great Eastern Archipelago generally that scope is afforded for identifying the trees and preserving them from extermination. The fear is expressed that commerce will not long be able to supply the demand for gums to cover electric cables, which raises a feeling of surprize that science has not, ere now, discovered a substitute in the shape of some artificial composition. That such a discovery will some day be made seems more probable than that sulphate of quinine will be superseded by an artificial compound. The difficulty of identifying the gutta trees in the forests is said to be increased by the small size of the blossoms, by the fact that blossoms and fruits do not co-exist on the trees, and that the trees themselves are, when fully grown, very tall. The natives who make their living by collecting the gum can give but vague information, their accounts of the number of trees they fell to secure a picul of gum (133⅓ lb.) varying from 100 trees to 250. Heer Burck believes that the major portion of the trees which produce gutta-percha are as yet unknown to science. There is, therefore, wide scope for research by him or some other naturalist. The most varying products go into the market by the same name and are often mixed together, only to be separated by an expensive process before being used to coat cables. Local prices are mentioned which vary from *f*30 per picul to *f*100. Many of the trees resemble durians in shape and the mangosteen in foliage. After the conclusion of his investigations in the Padang country, Heer Burck promises further information. As matters stand now, we imagine Dr. Trimen is able to tell the Ceylon Government what are the best trees to be cultivated or introduced, and we observe that several species or varieties have at Buitenzorg grown readily from seed.

SOME OBSERVATIONS ON GUTTA-PERCHA.

By W. BURCK, *Asst. Director.*

(Translated from the original Dutch for the "Tropical Agriculturist.")

It may be termed a remarkable and at the same time fortunate fact, that during the last few months attention has been drawn from so many different quarters and independently of each other to the great importance to industry, science and commerce of a closer acquaintance with the plants which yield the above-mentioned substance.

Remarkable, not because the subject is now for the first time brought under discussion, and that the value of this product had not been already for a long time known, and the necessity had been recognized of measures being taken against the rough methods of cultivation of gutta-percha-producing plants, but rather because during the last 20 years very little has been said about it.

I have called the fact fortunate in the highest degree, because the production of this substance during the last few years has diminished to such an alarming extent, whilst its indispensability in industry, especially for the insulating covering of telegraph wires, is more and more recognized, that it is beginning reasonably to be feared that very shortly the time will arrive when commerce will no longer be able to supply the large demand.

From the scientific point of view it was M. Beauvisage, who in his *Contribution à l' étude des origines botaniques de la Gutta-Percha*, Paris, 1881, gave a careful and critical review of what was known of the botanic origin of this important substance, which review may be said to be of so little value, that the words of Jungfleisch, Professeur à l' école de Pharmacie, an be applied in this case, who testified regarding the knowledge of the chemical composition of gutta-percha "que tout ce qui a été écrit sur ce sujet est entièrement à refaire" [that all that has been written on this subject will have to be done over again].

It was in the same year 1881 that the Director of the Public Botanic Garden at Buitenzorg, impressed with the importance of the subject from a scientific as well as from an industrial point of view, a few months after his arrival in Netherlands India instituted an investigation into everything bearing on this subject that was to be had in the Herbarium and the Museum of the Botanic Garden.

The result of this investigation was so unsatisfactory, that he felt obliged to call in the assistance of various heads of provincial governments that they might by their kind help throw some light on this dark question. The better to accomplish his purpose he arranged that at the same time through the Director of the Colonial Museum at Haarlem a collection of specimens of similar substances should be applied for on behalf of that Museum. Accordingly, he at once applied to the Governor of the West Coast of Sumatra, the Residents of Palembang, Banka and the western portion of Borneo, as well as to the Assistant Resident of Sintang, for the purpose of obtaining as complete as possible a herbarium of the plants which produce indiarubber, gutta-percha, varieties of gum and resin and allied substances. It was also asked that to the above might be added a specimen of the substance as it comes into the market, together with, specially of the groups of indiarubber and gutta-percha, a little of the fresh milky juice, preserved from spoiling by the addition of an antiseptic, in order that a chemical analysis might be rendered possible.

This application was met with the greatest willingness, and in March of the following year the Public Botanic Garden received from the Resident of Banka a well-chosen collection of twenty-eight different varieties of milky juice in stoppered bottles, with a careful description of the use by the natives of the tree and

the produce obtained from it, besides a branch with leaves for identification.

Not less valuable were the other gifts of herbaria with the addition of specimens as they are brought into the market by the collectors. In the very first place must be mentioned the extensive collection brought together with much trouble by the Controleur J. F. A. de Rooij of Soepayang, who accompanied this collection with a herbarium as complete as possible, and a detailed report on each variety separately.

This gift and the not less choice collection of the Controleur Van der Ploeg of Soengei Pagoe and 12 Kottas will be each dealt with below.

Quite independently of these efforts of the Director of the Public Botanic Garden the subject was soon taken up heartily and with ardour in other quarters.

Hr. Ten Brummeler, Chief Inspector, head of the post and telegraph service in Batavia, taking occasion from an important motion carried at the Coogrès des Electriciens held in the autumn of 1881 at Paris, in which the desirability was expressed, that, in countries which yielded the substances referred to, rules should be laid down for the cultivation of the trees from which those varieties of gums were drawn, shortly after his return from Europe in April 1882 induced the Director of Municipal Public Works to draw the attention of the Government to this subject, that means might be taken to preserve the trees which yield these products from entire destruction and by plain directions to atttain to better cultivation.

When Government showed that they were deeply impressed, and that they also took an interest in this subject, the Director of the Local Board of Administration was, on a subsequent recommendation of the Director of the Public Botanic Garden, requested by a Government order to obtain reports on the occurrence, the production and the raw product of both of the plants of Java which, according to Hasskarl, produce gutta-percha—the *karet andjing* and the *karet moending*, whilst the undersigned received orders to proceed in the month of September following to Moeara Lahoe in the Pa lang hillcountry in order to institute *in loco* an investigation into the botanic origin of these plants as well as into the climatological conditions necessary for their good growth.

Meanwhile, at the request of the Director of Municipal Public Works, a collection of specimens of gutta and caoutchouc was made by the Local Board of Administration through the under officials, which is certainly the finest and most complete that has ever been seen on this earth.

This collection was placed in the hands of Hr. Ten Brummeler and sent to the International Colonial and Export Exhibition at Amsterdam, accompanied by an exhaustive list of the most interesting details regarding the place of growth, the mode of culture, the soil of the land on which the plant grew, the value of the produce in commerce, &c., a collection that must undoubtedly have attracted the attention of every commercial and scientific visitor to the Exhibition.

The list was printed in the *Tijdschrift voor Nijverheid en Landbouw in Nederlandsch-Indië*, Vol. XXVIII, Part I., and it cannot fail, as Hr. Ten Brummeler intends it should do, to awaken the interest of the large landed proprietors and managers of agricultural enterprizes. Duplicates of the greater number of specimens sent to Amsterdam with the addition of some received later will be sent by Hr. Ten Brummeler to the exhibition to be held at Buitenzorg in September next, whilst at its close the whole collection is, with the greatest liberality, to be handed over to the Director of the Public Botanic Garden to be deposited in the Museum.

Meanwhile, the copious information received from Banka and the Padang hillcountry placed the Director of the Public Botanic Garden in a position to make effectual attempts at the task of performing an experiment with the varieties which, so far as can be judged provisionally, yield gutta of good quality, by growing these on a somewhat extensive scale in the economic garden at Tjikeumeuh. To this end the assistance of the heads of the Western Government was once more called in for the procuring of large quantities of seed of those plants which evidently yield the best commercial varieties, and it was not long before the Public Botanic Garden received from the Resident of Banka a large quantity of seed which, at this moment, has grown in the economic garden to a respectable height and promises to be a fine plantation.

From the Padang hillcountry seed could not be expected so quickly; the application was received after the fruiting season of the trees, and as these, so far as we know, blossom but once a year, the seed cannot be expected before the end of the current year. Through the intervention of the Director of the Local Board of Administration, the Public Botanic Garden at the same time received most interesting information from the Factory of the Netherlands Trading Company regarding the localities from which the gutta-percha produced in our archipelago is exported, and the quantity of the exports of the last three years, besides other not less interesting details regarding the manner of collecting the sap, the age at which the tree is felled, &c.

In apparently total ignorance of what had been done both on the part of the Government and by private persons in [Netherlands] India, Hr. F. W. Van Eeden, Secretary of the Commercial Company and Director of the Colonial Museum at Haarlem, wrote an article which, under the title of "Tough, but No Politics," appeared in the March number of the journal issued by the Netherlands Company for the Promotion of Industry. Hr. Van Eeden brought together succinctly all that was known on this subject with the object of attracting the attention of commerce and industry to this product.

Finally, there appeared in the subsequent number of the same periodical an essay on the different varieties of gutta of South-east Borneo from the pen of Hr. Schlimmer, in which many interesting facts were given, and to which I hope to refer more fully hereafter.

The reason why I wished to add one thing and another to the literature on this subject is not that I am as yet in a position to supply facts of importance on the botanical side of the question.

The inquiry instituted thus far by me is of a very preliminary character and does not yet admit of the drawing therefrom of important results. The herbarium material available in our Museum and that furnished to us by the abovementioned collections was for the most part too incomplete for the varieties to be determined botanically. The blame of this must not be referred entirely to insufficient care bestowed on the collection: our Museum in not the only one which does not possess complete herbarium specimens of gutta-percha-yielding plants; the same may be said of all museums in the world both in the tropics and in the great and world-famed European herbaria.

Even the best-known gutta-percha plant, the *Dichopsis Gutta* Benth. (*Isonandra Gutta* Hook.), is found in good specimens in scarcely any collection of plants, and M. Beauvisage and Prof. Baillon of Paris, who a couple of years ago especially were greatly interested in this matter, were able only after very great trouble to procure a single authentic specimen of this plant from the British Museum, and even that was far from complete, and had not a single opened blossom or ripe fruit.

The incompleteness of the herbarium material and the extremely limited knowledge of the botanical

origin of these plants, which is naturally very closely connected therewith, are due chiefly to the difficulty of collecting material, in which all the parts necessary for the description of the plant are present. Most of these plants appear to blossom but once a year, the blossoms are besides small and not readily recognizable, the trees all attain to a respectable height, and to a great extent have their crowns concealed by other forest trees, which makes it all the more difficult to determine whether they are not even then covered with blossom; at the time when the fruits ripen no blossom is to be had, and besides this by far the most are found growing in the interior of Borneo and Sumatra, to which parts very few European naturalists have hitherto penetrated.

Almost all that is at present known of these interesting plants is founded upon what has been related regarding them by natives—truly not always the most trustworthy source of information.

Regarding the chief points, all information so far tends to show that it is needful to receive as truth everything with the greatest reserve.

I will take but one example: it is absolutely unknown how much gutta can be obtained from a tree by felling or tapping.

According to Von Gaffron a well-grown tree should give 12 katties after *felling* and 1 katti at *tapping*. Prof. De Vriese however mentions a tree 39 feet high and 5 feet in circumference which yielded on *felling* 2 10-16th katties, whilst a younger stem of 32 feet in height and 3 feet in circumference gave on *incision* 1⅛ katti; now, since according to general opinion the quantity of gutta to be obtained increases with the age of the tree, the quantity obtained by the last means should be at least half, if not more, of that obtained after felling. According to Von Gaffron there is thus obtained 1-12th, according to Prof. De Vriese at least half of the total quantity to be got.

According to the abovementioned report of the Factory of the Netherlands Trading Company and the article of Hr. Schlimmer there were formerly found Djati Sambon trees which yielded 10 to 20 katties of gutta each, whilst now for the same quantity 50 to 60 trees must be felled, that is 250 to 300 trees for a pikul; whilst on the other hand it is stated (*Tijdschr. Nat. ver.*, Pt IV., p. 420) that the same quantity is obtained from 100 trees.

I take this simply as a specimen out of many, and only to give an example of how little faith can be put in reports. What, however, should interest the native more, who makes his living by gathering gutta, than the knowledge of the quantity of sap which a tree of a certain circumference, say of the thickness of a coconut tree, produces?

If the information on this point is conflicting, how can we build on the trustworthiness of other particulars?

I shall dwell no longer on this subject, but hope to be able to furnish more exact data regarding it hereafter. The provisional examination at the herbarium has in the first place given me the assurance that gutta-percha is a product of very different plants, and further that most of these plants are entirely new to science, and have never been described.

The conviction, that for each future investigation it is absolutely essential to know as far as possible under what name the gutta-percha comes into the market, has chiefly induced me to complete the list of products drawn up by Hr. Ten Brummeler with the data furnished to us and the specimens in our herbarium.

I consider the work of Hr. Ten Brummeler of importance as a basis for all further investigations; the more complete the additions to it can be made, the greater will be its value.

Botanical investigation must determine later on what various names are given in the different places of growth to one and the same product, and *vice versa* how far the same name is given to products of the most varying origin.

That both are actually the case, I hope to make evident immediately. If that is once established, and at the same time the botanical origin of the various products known, a better estimate can be formed of the commercial value of a certain specimen.

The confusion in this matter is so great that no single European merchant is in a position to give with any certainty information regarding the good qualities or the particulars of a single variety of gutta-percha of commerce. The fault ascribed in Europe is chiefly to adulteration and mixing with inferior qualities by middlemen. This is undoubtedly one of the reasons, but the chief one is certainly this, that the most varying products come into the market under the same name.

"The very first question," says Beauvisage, "I asked the merchants was, which were the best kinds of gutta-percha. One of them referred me to the Macassars, another to the Sumatras and some Bornees, another to the Bandjirmassins, and another to the Singaporee, and above all to the *balata* of Guiana, each of them attaching little value to the product which the others appreciated most, or at any rate not mentioning it by the same name."

One is so readily led to adopt the commercial value as a basis for judging of the quality; certain particulars, which I shall give below, will show clearly that at present the commercial value of the same product at the different places of growth is very varying, and that it is not possible to infer an inferior or better quality from the value of one specimen.

The examination of our collection of dried plants has taught me that the following names have been given to the product of one and the same tree* :—

1. Balam pipis—Soepajang (Pad. hillcountry);
   Balam tandjong—Palembang;
   Balam tjabee—Palembang;
   Balam tandoek—Palembang;
   Njatoh—Borneo (Soekadana, W. Borneo, according to T. and B.);
   Keelan—Banka;
   Getah Seundek—Malacca (according to Beauvisage);
   Balam Kembang—Moesi Oeloe.

These different names are given to the gutta-percha obtained from *Keratophorus Leerii* Hasskl.

Balam pipis, No. 104 of the list of Hr. Ten Brummeler, is undoubtedly the same as that mentioned above from the same place of growth.

Boenga tandjong from the Lima Poeloeh Kotta, No. 86 of the list referred to, is most probably the same as the Balam tandjong and Balam tandoek of Palembang mentioned here.†

Hereunder ought also apparently to be counted Nos. 4, 8, 9, 10, 12, 15 and 16 under the name of Getah Keelan of Banka, at any rate some of them, for according to the remark appended Getah Keelan is the product of two different trees, viz., of one with white and another with brown bark. However, I have no herbarium from the collection of Hr. Ten Brummeler to decide with certainty on this point, and for the same reason it cannot be settled whether Getah Seendi, Nos. 35, 43, 44, and 45, Seendik, No. 37, Sontik, No. 56, and Seendai, No. 95, names which bear a great similarity to Getah Seundek (according to French pronunciation) of Malacca, is also the product of *Keratophorus Leerii*.

*I must explain here that the following are only provisional results. It is possible that later examination of more complete material will show that I have here and there fallen into error.

† The Latin name, however, of No. 86, "*Ceratophorus heerchasiek*," is clearly a clerical error for *Ceratophorus Leerii* Hassk. (Hasskarl).

2. Ngiatoe doerian, Borneo ;
Getah njato doerian, Borneo ;
Balam Soesoen of Padang ;
Balam doerian of Soepaijang ;
Kajoe balam of Solok ;
Balam tembago of Boujol ;
Balam tembago of Soengei Pagoe and 12 Kottas ;
Gutta of Rioun ;

are in like manner the same product under different names. I should be inclined to add to these the Balam laoet and Balam darat, both of Soengei Pagoe and 12 Kottas, did it not appear from the information furnished to us by the Controleur Van der Ploeg that they differ in the color of the blossom. The varieties of gutta mentioned under 3-7 have also a common origin.

3. Njato doerian of Sumatra similar to Njato doerian of Sambas (Borneo) and different from the same name mentioned under 2.

4. Balam of Palembang ;
Kajoe balam tembago of Battang Baros ; and
Getah balam tembago of Loeboe Along.

5. Getah njato of Borneo similar to Balam Sonté of Palembang 1st sort.

6. Getah Balam of Palembang similar to Balam troeng of Palembang.

7. Balam tembago of Priaman ;

Isonandra gutta Hk. from the Botanic Garden (not similar to the actual *I. Gutta* Hk. or *Dichopsis Gutta* Benth.) ;
Getah tuban-mera (according to Beauvisage) ;
Balam abang of Palembang,

and most probably all the same as those described by Prof. De Vriese as *Isonandra Gutta var. oblongifolia* de Vr. of Borneo and *Isonandra Gutta var. Sumatrana* Miq. of Sumatra. Probably also :—

Getah taban of the Straits ;
Getah tuban of the Straits ;
Getah merah No. 1 of the Straits ;
Ngiatoe merah and Ngiatoe To-oen of S. E. Borneo.

8. Balam tambaga of Soepayang.

The varieties of gutta-percha here detailed under 1-8 are, so far as can at the moment be said with any certainty, the product of eight different plants. In five of the eight we meet with the name of *Tembago* or *tembaga*, all coming from Sumatra.

The name *Doerian* also appears to be given to various plants ; the two that bear this name in Sumatra are not similar. The *njatoe-doerian* of Borneo on the other hand is similar to one of the *njato-doerians* of Sumatra.

In the list of Hr. Ten Brummeler among the commercial varieties of Sumatra several are met with under the name Getah Balam (see Nos. 33, 34, 38, 54, 55, 59, 60, 75, 76); others under the name of Balam Baringin (Nos. 97, 101, 102, 111, 112, 114, 115) or Getah Baringin (No. 87) or Balam waringin (No. 50), &c., &c.; it is evident from the above example that one can have no certainty that what comes into the market as Getah Balam of Sumatra is always the product of the same tree.

When therefore a merchant one year obtains from Sumatra a Getah Balam which appears to him to be of superior quality, it must not be ascribed directly to adulteration, if the gutta which he receives later on under the same name from Sumatra appears to be of a far inferior quality.

The above notice of various names for the same product teaches us at the same time how little we must rely upon the evidence of commercial value for a judgment of the quality of a variety of gutta. I shall only choose as an example the product that is also best known botanically : the gutta-percha derived from *Keratophorus Leerii* Hssk. mentioned under 1.

The price of the Banka *Koelan* is *f*45 to *f*60 the pikul of 62½ kg.

The same gutta under the name of *balam pipis* of Soepayang has an export value of *f*80 per pikul, whilst as *Boenga tandjoeng* of Lima Poeloeh Kotta it has no exact value, and can only be used for mixing.

If the *Kolan* of Borneo is the same as that of Banka (*Koelan* is pronounced *Kolan* in Banka), the difference is even greater, for the Borneo gutta mentioned has a value of *f*116·50 per pikul.*

I shall now leave the subject to return to it when I am able to collect more data. Nor shall I at present attempt a decision of the relative values of the different samples so far as they can be fixed at first sight. I shall simply append a list of the names of the commerical varieties of Borneo, Sumatra, Banka, Billiton and Java, so far as these are not given in the list of Hr. Ten Brummeler, from the information furnished to us, as well as of the names of the samples preserved in the herbarium of the Public Botanic Gardens at Buitenzorg and of those which are found noted here and there in the literature of this subject. I have not included the varieties of caoutchouc, gums and resins in this list, hoping to refer to these on a future occasion.

GUTTA-PERCHA OF BORNEO.

(*Compare Nos. 17-28 and 61-74 of the List of Hr. Ten Brummeler.*)

Taken from the notes of Hr. J. W. Schlimmer (Journal of the Netherlands Commercial Co., April 1883 :—

(i) Native name, *Njato Sambon.*—Place of origin, S. E. Borneo.—This is apparently the same plant as that mentioned in Nos. 17, 22 and 28 of the list of Hr. Ten Brummeler. The Njato-Sambon tree grows best in red, fertile soil more or less mixed with sand, and preferably at the foot of a mountain or on the mountain itself. The gutta-percha is of superior quality, but this rule is not without exception. The further description of Hr. Schlimmer makes it probable that the gutta of two different trees is brought into the market under the same name.

(ii) *Njato matakatam.*—S. E. Borneo (only in the territory of the Orang Ot).—Gutta of about the same value as that of the Njato-Sambon tree. The tree usually grows at the foot of the mountains, and is similar in height and thickness to the Njato-Sambon.

(iii) *Njato matakatam.*—S. E. Borneo (Province of Sampit). —This yields gutta of inferior quality, known also under the name of *Tanggong.*

(iv) *Njato nangka.*—S. E. Borneo.—The leaves of this tree greatly resemble those of the Nangka trees. The gutta is brought into the market as *Getah Sambon.*

(v) *Njato waringin.*—S. E. Borneo.—This is perhaps the same as the *Baringin* Nos. 18 and 27 of the list of Hr. Ten Brummeler. The tree resembles the *waringin.* The sap is pure white, and when boiled resembles white wax. The superior gutta is very tough, while the inferior is very sticky.

(vi) *Njato hangkang.*—S. E. Borneo.—This, apparently the same as Nos. 21, 23 and 24 of the abovementioned list, is met with only in water and in marshes. The tree has numerous aerial roots. The sap is white, very sticky, and, when it is boiled, brittle.

(vii) *Njato Sendok, Njato tinggang, Njato Bawoy, Njato roepoy.*—S. E. Borneo.—The sap of Njato Bawoy is not used ; that of Njato Sendok, tinggang and roepoy is of inferior quality, and is used solely for adulterating good gutta.

The following is taken from the "Notes on Gutta-Percha of S. E. Borneo." communicated by Prof. de Vriese from discoveries by James Motley (*Nat. Tijdschrift voor Ned. Ind.*, P't. XXI., 1860) :—

(viii) *Ngiatoe merah* and *Ngiatoe To-oen* (*? Io-oen*).—S. E. Borneo.—This is, according to Motley, the gutta tuban of the Straits of Singapore, the actual *Isonandra gutta* Hook. (*Dichopsis gutta* Benth.) ; known also under the name

* In the Report of the Royal Gardens at Kew, 1882, there occurs the following valuation of the worth of gutta-percha (most probably Gutta taban mera is here referred to, see sub 7) :—"Assuming each picul of 133⅓ lb. of the best qualities to represent the yield of 10 (!) trees and to be worth £45" (!) &c. The gutta referred to is the same as the Balam abang, and this has a commerical value of *f*80 to *f*100.

of gutta merak No. 1 and gutta taban. A very reasonable doubt has however been raised by M. Beauvisage as to whether this plant is actually the same as that described by Hooker as *Isonandra gutta*. The plant, the product of which is known under the name of Gutta taban merah, is according to M. Beauvisage the same as *I. gutta* Hook. *var. oblongifolia* de Vr. described by Prof. de Vriese in *Tuinbouw-Flora* III., and *I. gutta var. Sumatrana* Miq. The same plant, of which only a leaf is figured in the *Tuinbouw-Flora* (the other figures relate to quite a different plant), is found in the Buitenzorg Botanic Garden, as well as in the Academy Garden at Leyden, but does not produce ny flowers. We must further remark here that we are with Beauvisage also of opinion that De Vriese and Hooker had no right to consider this as a variety of *Isonandra gutta*. Regarding the probable synonyms of the product of this plant in commerce, compare what I have said on the subject above under 7.

(ix) *Ngiatoe Bintang.*—S. E. Borneo (Banjoe-iran).—*Isonandra dasyphylla* Miq. The gutta is used for adulteration of gutta-percha No. 1. It is however doubtful, as the substance is yielded in but small quantities by the tree.

(x) *Kotian.*—S. E. Borneo (Banjoe-iran).—*Isonandra Motleyana* de Vr. The tree yields plenty of sap but of bad quality. The oil which can be extracted from the seeds has the taste and smell of oil of bitter almonds, is used in confectionery, and is valued very highly in Bandjermassin.

(xi) *Ngiatoe-poetih.*—S. E. Borneo (Banjoe-iran).—*Isonandra macrophylla* de Vr. According to Motley probably the tuban sanah of the collectors of Singapore, from which the resin No. 2 is derived.

(xii) *Ngiatoe-wangi.*—S. E. Borneo (Banjoe-iran).—*Isonandra? Benjamina* de Vr. This gives a brilliant red gutta, which greatly resembles the true "Njatoe merah." This plant is said to be very rare and to be confined to hilly country.

(xiii) *Ngiatoe-doekong* or *N. djoekong.*—S. E. Borneo (Banjoe-iran).—*Bassia ? sp.* Gives a good quantity of gutta of the second sort and of a very white colour. The great proportion of gutta which is exported from Bandjermassin is said to be obtained from this variety.

(xiv) *Ngiatoe-renkang.*—S. E. Borneo (Banjoe-iran).—*Isonandra xanthochyma* de Vr. The gum (gutta) is yellowish in color and of the second sort.

(xv) *Ngiatoe-tinang.*—S. E. Borneo (Banjoe-iran).—*Isonandra quercifolia* de Vr. Regarding the characteristics of the gutta of this plant nothing is related by Motley, even less than those of *Isonandra macrophylla* de Vr.*

The following notices are taken from a communication by Von Gaffron published in the *Nat. Tijdschrift voor Ned. Ind.*, Pt. XVI., p. 226:—

(xvi) *Getah-pertja waringin.*—Borneo along the Kapoeas river.—Perhaps similar to *getah bringin* of Sintong Nos. 61 and 62 of the list of Hr. Ten Brummeler. This gutta is of the best sort. The tree grows in hilly regions on yellow clayey soil and agrees closely with the waringin. The stem and sap are white. (Compare what is said above regarding the gutta of the same name from S. E. Borneo.)

(xvii) *Getah-pertja doerian.*—Borneo along the Kapoeas river.—Perhaps similar to Nos. 62, 64 and 65 of the list referred to. The gutta is of the second sort. The tree is also found in hilly regions. It much resembles the doerian, and its sap is originally reddish.

(xviii) *Getah-pertja poeloet.*—Borneo along the Kapoeas river.—This yields the third sort of gutta of commerce; the tree resembles the champak; the sap is brownish.

(xix) *Getah-pertja papoea, Getah-pertja rana.*—Borneo along the Kapoeas river.—Both varieties are little sought after in commerce.

* It is remarkable and hitherto inexplicable that none of the eight last-named varieties of S. E. Borneo gutta-percha mentioned by Motley agrees even in name with one of the nine varieties from the same part of Borneo referred to by Hr. Schlimmer. Yet some of them, such as the Ngiatoe merah and especially Ngiatoe toekang, appear to be of the greatest importance in commerce. Hr. Ten Brummeler also mentions two (three) varieties, Nos. 19, 20 (and 18 ?), which neither Motley nor Schlimmer gives. We possess none of these S. E. Borneo varieties in our Herbarium, so that it is impossible for me to tell if in this case also the same product is brought into the market under different names.

(xx) *Getah-pertja katella, Getah-pertja djankar, Getah-pertja kladi.*—The gutta of these three varieties is used only for mixing with getah-pertja waringin. According to Von Gaffron they could, by certain manipulations, be made suitable for industry. According to Teijsmann and Binnendijk *Getah-djankar* is the product of *Isonandra calophylla* (T. B.).

Dried plants and specimens of gutta preserved in the Herbarium and the Museum of the Botanic Garden:—

(xxi) *Ngiatoe-djeloetong* 2nd sort.—Borneo along the Kapoeas river.—Of this there is a branch with leaves in the Herbarium and two samples of gutta in the Museum. The gutta appears to me to be of bad quality; it is brown colored and brittle. Perhaps it is the same as No. 74 of Sambas. The plant exhibits some points of agreement with the *Isonandra calophylla* mentioned above, but cannot be further identified on account of the incompleteness of the sample.*

(xxii) *Getah-djantahan.*—Sambas.—A specimen collected by Hr. Zwager. The gutta is very brittle and appears to me to possess too little value.

(xxiii) *Njato doerian.*—Sambas.—*Ngiatoe doerian* 1st sort. —Borneo (the habitat is not more definitely mentioned).—Herbarium specimens Nos. 6,558 and 14,600; the dried plants certainly represent two different varieties (on this see what I have said above under 3).

(xxiv) *Njatoh* —Borneo (habitat not more definitely mentioned).—This is the *Keratophorus Leerii* Hassk. mentioned above under 1.

(xxv) *Getah-Njato.*—Singkang.—Of this gutta our Museum possesses two specimens: the first apparently of very good quality, the other on the contrary very bad.

(xxvi) *Getah-pertja.*—Borneo (habitat not more definitely given).—Two specimens under this name in the Museum, both collected by Niclou; apparently derived from two different trees; the one specimen appears to me to be of superior quality, the other on the contrary of very little value.

Taken from the *Nat. Tijdschrift van Nederlandsch Indië*, Pt. IV., p. 420:—

(xxvii) *Getah.*—Soekadana (W. Borneo).—According to the late observant Commander Baron von Eck there are two sorts of gutta brought into the market at Soekadana. One sort is white and is commoner than the other or brown sort. The white, however, is only half the value. It is asserted however by the Resident of the western division of Borneo that both sorts have the same origin, but that the originally white gutta is coloured lest it should otherwise be pronounced bad. A sample of the brown gutta of Soekadana is in our Museum and is evidently of good quality.

Nat. Tijdschrift, Pt. VI., p. 118:—

(xxviii) *Njato.*—Soekadana.—According to Teijsmann and Binnendijk, who however examined not the plant but only a specimen, this corresponds with *Balam tandock* of Palembang, the product of *Keratophorus Leerii* Hasskl. This is highly probable, as the Njato of Borneo mentioned above, of which I had no gutta but a dried plant at my disposal, appeared actually to be the *Keratophorus Leerii*.

(xxix) *Getah-pertja.*—Koetei river, east coast of Borneo.—Of the product of this plant I find nothing recorded.

Treacher, Colonial Secretary at Labuan (vide Kew Report 1881, p. 42):—

(xxx) *Gutta* or *Gniato elong, Gutta putch.*—North Borneo (Brunei).—The product of both these trees is brought to Labuan as *gutta cras*. According to Treacher the *gutta merah* of commerce is the same as the *gutta putch*, but polluted with double the quantity of bark scrapings. Further, according to the Kew Report *gutta elong* is very probably the product of *Dichopsis gutta*. As, however, according to the same report, Treacher had got no authentic specimen, it is more prudent to wait for further information regarding it. *Gutta putch* is probably the product of a species very nearly allied to *Dichopsis gutta* Benth.

(xxxi) *Gutta (Gniato) Maresah.*—North Borneo (Brunei). —Gutta of inferior quality.

(xxxii) *Gutta (Gniato) Durian.*—North Borneo (Brunei).—This gutta is not imported in a pure state. It is of in-

* Whether this plant is the same as, or allied to, that which yields the *Gutta jelutong* of the Malacca peninsula, cannot be said at present. The latter is attributed to *Dyera laxifolia*.

ferior quality and is frequently mixed with the *gutta cras*.

Taken from Montgomery according to Beauvisage, p. 12:—

(xxxiii) *Gutta-Girek, Gutta-Tuban, Gutta-Percha*.—Sarawak.—All, according to Dr. Montgomery, varieties of one and the same tree found in Singapore, Johore, Malacca, Coti (S. E. Borneo), and according to the observation of Sir James Brooke in abundance in Sarawak. Beauvisage doubts whether these are actually varieties of *Dichopsis Gutta* Benth.

In conclusion I may just mention that according to Professor De Vriese mention is made by Thomas Oxley of seven (? !) varieties of gutta-percha trees, which to the eye all resemble one another, and the difference between which can be told only by the colour of the wood. Of these seven varieties only three produce the true gum. Those which yield the true Gutta-Tuban in Borneo are:—

1st, the tree with yellow wood;

2nd, the tree with reddish wood;

3rd, the tree with white wood; the white yields the best gutta, the 3rd only a gum of inferior quality.

GUTTA PERCHA OF SUMATRA.

(Compare Nos. 32-60, 75-112, and 114-115 of the List of Hr. Ten Brummeler.)

The following particulars are taken from the list drawn up by Hr. Ten Brummeler and belonging to the Buitenzorg collection:—

(i) *Getah balam tembago* No. 1, *Getah balem tembago* No. 2, *Njatoeh balam tembago* No. 1, *Njatoeh balam tembago* No. 2, *Getah Kajoe Kerang, Getah Njatoeh, Balam Bentoengon, Njatoeh Selendit, Getah Kajoe balem*.—Tanah Datar.—The trees which yield gutta-percha are mostly found in extensive forests in mountainous regions and on sandy soil. They much resemble durian trees, and the leaves those of the mangosteen. The age necessary before the trees are fit for tapping is not known with certainty. Some fix this approximately at 20 years. The gutta is obtained in the following manner. The tree is cut down and then ringed at equal distances of about one heto (about two decimeters). Under each ringed portion some kind of vessel is placed to catch the dripping gutta, which process is terminated in 3 or 4 days. The gutta is then collected, boiled in iron kettles (Kantjah), and in some measure, though very incompletely, purified. The gutta is then allowed to cool, until it can be laid on a plank in long ropes, which are then folded into blocks either with the hand or foot or with a piece of wood. The quantity of gutta obtained from a full-grown tree is reckoned at 3 to 8 gantangs. The quantity which is exported of each sort per annum cannot be given, as there is not the least check upon it. According to general opinion, the production is declining every year, the result undoubtedly of the injudicious system of gathering the product. The prices at which the various sorts were sold per pikul of 62½ kg. in the sub-division were as follows:—

Balem tembago (red gutta)	...	*f*80
Kajoe balem („ „)	...	„60
Kajoe kirang (white „)	...	„35
Kajoe balem bentoengan (red gutta)	...	„60
Njatoeh balem tembago	...	*f*70 to „100
Njatoe haringin ...	...	„40
Njatoeh Selendit ...	...	„25 „ „30

Planting takes place by seed.

Mentioned by Teijsmann and Binnendijk (*Tijdschrift Nat. Ver.*, Pt. VI):—

(ii) *Balam tandoek, Balam tjabe, Balam sonte, Balam troeng*.—Palembang.—Balam tandoek is obtained from the plant described by Teijsmann and Binnendijk under the name of *Azaola Leerii*, which name was afterwards altered by Hasskarl to *Kerotophorus Leerii* (*Ceratophorus Leerii*, *Ceratephorus Lecrii*). I have already noticed above that the Balam tjabe mentioned here has the same origin. Hr. Van Leer, Health Officer of the 1st class at Palembang, to whom Messrs. Teijsmann and Binnendijk are indebted for the forwarding of the specimens, remarks that the pohon balam is a tree very frequently met with in the Palembang district on high lands, attaining to a great age and exceptionally large girth. The bees form nests on the pohon balam, and on this account the tree is planted and cultivated more for the wax than for its gutta-percha, and as with the gathering of the gutta is necessarily connected the destruction of the tree the native engages very little in this occupation, and then only when he thinks that the tree is approaching its end and will therefore produce no more wax. The usual native method of collecting and preparing the gutta-percha consists in cutting the tree completely down, cutting off the crown, and making a number of incisions in the stem and the principal branches, &c.

(iii) *Balam tembaga*.—Padang.—Regarding the gutta of this tree I find nothing recorded by Teijsmann and Binnendijk: this is probably the same as No. 77 of the list of Hr. Ten Brummeler; this cannot however be decided with certainty without a herbarium examination.

(iv) *Balam*.—Palembang.—Under this name Messrs. Teijsmann and Binnendijk had two plants which represented two different varieties. Of the gutta nothing was known to them. With which of those mentioned by Hr. Ten Brummeler this balam corresponds cannot be ascertained.

Plants in the Herbarium of the Public Botanic Garden, collected by Controleur Van der Ploeg:—

(v) *Getah balam bringin*.—Soengei Pagoe and 12 Kottas.—The substance which comes into the market, and which surpasses other sorts of balam, is obtained from the milky sap by boiling. The blossom is white, the fruit is the size of a large pea.

(vi) *Getah balam tembaga*.—Soengei Pagoe and 12 Kottas Sap of inferior quality to that of Balam bringin. The blossom of this also is white, the fruit is red and of the size of a small marble.

(vii) *Getah balam laoet*.—Soengei Pagoe and 12 Kottas.—The substance of inferior quality and brittle when it is old. The blossom is of a red color.

(viii) *Getah balam darat* or *Getah balam pirang*.—Soengei Pagoe and 12 Kottas.—The gutta is not sold in the market by itself on account of its bad quality, but in most cases is mixed with other sorts of balam and so brought into market. The colour of the blossom is yellow.

Specimens, herbarium and remarks received from the Controleur de Rooij:—

(ix) *Balam pipis*.—Soepajang.—Most probably similar to No. 104 of the list of Hr. Ten Brummeler. As I have already remarked above, this plant is the *Ceratophorus Leerii*. The tree grows above 2,000 feet above sea-level in humus soil in thick woods and needs shadow and moist ground (not marsh). The age is about a man's lifetime; the blossoms resemble those of the Tandjong; the blossoming season occurs generally in October: the fruits are pear-shaped, green and hard. On the manner of gathering the sap the details given in the list of Hr. Ten Brummeler should be consulted.

(x) *Balam doerian*.—Soepajang.—The plant mentioned here is most probably the same as No. 106 of the list abovenamed. For the synonyms, consult what I have said above sub 2. The blossoms greatly resemble those of Tandjong, but are larger and whiter. The fruits are green and round like those of terong gloegoe but having a kernel. The gutta is darker colored than that of balam pipis. It is obtained in the same manner.

(xi) *Balam tambaga*.—Soepajang.—Most probably similar to No. 103, but not agreeing with other varieties brought into market under the same name from other places in Sumatra. (See above sub 8.) In the place of growth this agrees with balam pipis and doerian. The blossoms resemble those of Tandjong but are smaller; the fruits round as a ball, hard and green. The gutta is of inferior quality and darker colored.

Preserved in the Herbarium and presented by different persons:—

(xii) *Kajoe Balam*.—Solok.—Herbarium Botanic Garden No. 969.

(xiii) *Balam tembago*.—Boujol.—Herbarium Botanic Garden No. 980.

(xiv) *Getah Njato doerian*.—Sumatra? or Borneo?—Herbarium Botanic Garden No. 14,608.

(xv) *Balam soesoen*.—Loeboe Kilangan (Padang Bes.)

The four lastnamed are most probably different names for the same plants (see above sub 2).

(xvi) *Njato doerian*.—Sumatra (place of growth not more definitely mentioned).—Herbarium specimen collected by Hr. Styman (see above sub 3).

(xvii) *Getah Balam tembago.*—Locboe Along.—Herbarium Botanic Garden No. 970.

(xviii) *Balam.*—Palembang.—Herbarium Botanic Garden No. 977.

(xix) *Kajoe Balam tembago.*—Battong Baroes.

The last three again are most probably one and the same plant (see above sub 4).

(xx) *Balam tembago.*—Priaman.—Specimen sent by Hr. Diependorst.

(xxi) *Getah.*—Sumatra.—Specimen sent by Hr. Diependorst.

(xxii) *Getah Balam.*—Palembang.

(xxiii) *Balam troeng.*—Palembang.

The last two again are like each other, and probably the same as that mentioned above, taken from the *Nat. Tijdschrift voor Nederlandsch Indië*, Pt. VI.

Specimens of gutta in the Museum of the Public Botanic Garden without connected herbarium of the plant from which the product is derived:—

(xxiv) *Balam abang.*—Palembang.—Specimens of gutta in our Museum collected by the English traveller H. O. Forbes.

(xxv) *Balam poetih.*—Palembang.—Specimen in the Museum.

(xxvi) *Getah balam kembang.*—Moesi Oeloe.—Specimen in the Museum.

(xxvii) *Getta-Pertja.*—Sumatra (without more definite indication of the place of origin).—Specimen in the Museum.

(xxviii) *Getah Koebang.*—Priaman.—Specimen in the Museum.

GUTTA-PERCHA OF BANKA.

(*Compare Nos. 4-16 of the List of Hr. Ten Brummeler.*)

Teijsmann and Binnendijk, *Nat. Tijdschr.*, Pt. VI, p. 119:—

(i) *Dadauw.*—Messrs. Teijsmann and Binnendijk enumerate three sorts of Dadauw, viz., Dadauw of Seroja 1st sort, Dadauw 2nd sort, and the Marawang Dadauw. The first, according to them, is the product of *Isonandra Gutta* Hk. According to information from Resident Schaap, the seeds of this lastnamed plant resemble those of the Sawo (*Minusops Bojeri* Dc.). From the dried kernel and edible substance is obtained, as in the case of the Sapiri (?), and the gutta itself, brown in color, is worth 15 dollars per pikul. Regarding dadauw 2nd sort nothing is stated; the Marawang dadauw however yields, according to Teijsmann and Binnendijk, a very bad brittle gutta. The herbarium of these three varieties of dadauw plants received from Resident Schaap is not in our Museum. On the other hand we possess four dried plants from Banka under this name, which represent perhaps four, at any rate three, very different varieties. Only one of them collected by Dr. Crookewit shows an agreement with the specimen lately sent to us by Resident Ecoma Verstege. The specimens of Getah dadauw in our Museum equally prove that the name *dadauw* in Banka is a very common name and that no particular species is designated thereby. Two specimens in particular appear to be very bad and brittle. Three other pieces on the other hand are evidently gutta of superior quality.

(ii) *Njato.*—Banka.—Enumerated by Teijsmann and Binnendijk. Regarding the gutta nothing is said.

Herbarium of the Public Botanic Gardens:—

(iii) *Njato.*—Banka.—Specimen in the Herbarium sent by Resident Ecoma Verstege. The product, which is obtained only in small quantity from the tree, is used solely for making birdlime, while the wood serves for household furniture and for making the oars of prahus.

(iv) *Njato darat* (from Batoe Roesa), *Njato riengoeng*, *Njato pisang* (from Djeboes), *Njato teroen.*—Dried specimens of the varieties of Njato here mentioned are in the Herbarium; Njato teroen alone appears to be the same as the abovementioned Njato of Resident Ecoma Verstege. The name *Njatoh* thus appears to have, like *Dadauw*, a very general signification; under this name are without doubt grouped very different plants.

(v) *Kolan* or *Koelan.*—This is probably the same as *some* of Nos. 4, 8, 9, 10, 12, 15, 16, of the List of Hr. Ten Brummeler. Not all however, as the description there given makes it most probable that this Koelan is the product of not one but two trees with differently colored bark. The Koelan of Banka, of which several plants are in our Herbarium and very fine specimens of gutta in the Museum, for which we have to thank in great part Resident Ecoma Verstege, is undoubtedly the *Keratophorus Leerii* mentioned above sub 1. The gutta appears to me to be of good quality. The product sent to Messrs. Teijsmann and Binnendijk in the year 1851 under this name was certainly derived from another plant which yielded an inferior gutta. I may here further remark that the Koelan, according to the information furnished by the Resident, grows as well in moist as in dry soil, that the tree produces a large amount of gutta, that the fruit is eaten and the gutta is used for making the handles of billhooks and for buckets, whilst the wood serves for household furniture and the oars of prahus.

(vi) *Ketiau.*—That this is the same as No. 7 of the List of Hr. Ten Brummeler is rendered improbable by the comparatively high value of this product, which does not correspond with the low value attached to it by Messrs. Teijsmann and Binnendijk.

(vii) *Katijau.*—This plant, a specimen of the sap of which has been sent by the Resident, is probably the same. Regarding the gutta it is only stated that the tree produces little and slowly.

(viii) *Djeloetoeng.*—Perhaps the same as djiloetoeng No. 13 of the List of Hr. Ten Brummeler. The tree yields gutta plentifully, but this is used only as birdlime, whilst the wood serves for the making of coffins and the fruits are eaten.

Specimens of gutta in the Museum:—

(ix) *Getah-pertja* No. 2.—A specimen of gutta collected by Teijsmann. Evidently of bad quality.

(x) *Balam tembaga.*—Do.

(xi) *Getah-pertja.*—Do. The gutta black and very hard.

(xii) *Getah broehi*, *Getah Poedock*, *Getah djeloetoeng*, *Ketiauw*, *Getah Kajoe barkit*, *Getah mentok*, *Getah Kajoe bakit*, *Getah Kajoe belangiran.*—Billiton.—Among these different varieties of gutta-percha there is little, judging from external appearance, deserving of special remark. Of none of these varieties do we possess any herbarium except of *Ketian*, which is according to Teijsmann the *Keratophorus longipetalus* T. and B. Further, I find an indication to the effect that *Getah djëloetoeng* is the product of *Alstoni spec.* We possess two specimens of *Getah djëloetoeng* however of very different appearance, but both without doubt of bad quality. Besides the herbarium of *Ketian* derived from *Keratophorus longipetalus* I find it also stated that this gutta is the product of *Siderozylon glabrescens* Miq. The two specimens in the Museum resemble each other greatly; it is however not possible to discover which gutta is the product of the first and which of the second of the plants named. Of *getah poedoek* also one specimen is very dark in color.

GUTTA PERCHA OF JAVA.

(*Compare Nos. 1, 2, 3; 29, 30, 31, and 32 of the List of Hr. Ten Brummeler.*)

(i) *Karet andjieng.*—Bantam, Samarang.—This is the plant described by Hasskarl as *Chrysophyllum rhodoneurum.* Regarding its product very little is yet known.

(ii) *Karet moending.*—Bantam.—*Kakosmanthus makrophyllus* Hasskl. According to Teijsmann this tree yields a dirty-white elastic gutta, which when fresh and after the watery particles have been evaporated by heat can be kneaded and stretched into all shapes. It is not soluble in hot water, but is very smooth and soft, so that it can be drawn out into the finest threads; in this state it is somewhat sticky but can be worked very well with the bare hands. After the lapse of time it loses this stickiness for the most part, and becomes a firm mass, which is, however, softer than that of *Isonandra gutta.* It has also not that woody appearance and is not so liable to split but is much more coherent. "If it is gathered in quantity, so that woody and other foreign matters get mixed up with it, it will probably have more agreement with the gutta of *Isonandra gutta, so that this new product may be regarded as a fine sort of gutta,*" &c. Since Teijsmann wrote this in 1850 (*Nat. Tijdschrift voor N. I.*, Pt. I, pp. 476,477) it appears that nothing further has been recorded regarding this variety of gutta, which, as appears from the foregoing, is far better known as regards its botanical origin than most of the other gutta-producing plants. Now however that

by Government order it has been notified to the Directors of the Local Board of Administration to obtain information regarding the distribution, the production and the product of this as well as of the *Karet andjieng* referred to above, it will soon appear whether the expectations entertained by Teijsmann will be fulfilled.

(iii) *Karet pantjal.*—Bantam.—This is according to Hasskarl the native name for *Sideroxylon attenuatum*, which, according to statements of Teijsmann, yields a gutta like that of the two abovenamed.

Recorded by Teijsmann (*Nat. Tijdschr.*, Pt. I, p. 497):—

(iv) *Tundjong.*—Lowlands.—*Mimusops Elengi.*—This more familiar plant yields a grey gutta of inferior quality.

(v) *Sawo.*—Lowlands.—*Mimuseps manilkara.* Yields a gutta like the foregoing.

(vi) *Sawo Manilla.*—Introduced.—*Sapota achras* or West Indian medlar; introduced from the West Indies into Java. The gutta is light brown in color, elastic and supple in water but hard and brittle when cold.

(vii) *Djengkot.*—Buitenzorg, &c.—*Bessia sericea.*—This yields a pure white gutta which is not so brittle as the preceding.

(viii) *Getah Pankalar, Getah Kiara, Getah Kendang, Getah Tierop, Getah Emberang.*—The five lastnamed varieties of gutta-percha were sent from the Preanger Regencies to the International Exhibition at Paris; I find nothing stated however regarding the comparative value and the appearance of the product.

June 1883.

After the conclusion of my investigation in the Padang hillcountry, I hope to be able to furnish further particulars on this question.

MORE ABOUT TEA.

In the *Home and Colonial Mail* of June 20 we find a far more extended report of the meeting of the Assam Tea Company, which we drew attention to the other day; and though we still maintain that the theory of the Chairman that "manuring would do the tea-plant little good" is an absurd one, we in fairness to him give his reasons for thinking so. He said that "he looked upon the tea-plant as a forest tree, and not an ordinary shrub or flower or plant which grew upon shallow ground. It sent its roots down as the chesnut or the ash. He mentioned those two trees because they were treated in this country very much as the tea-plant was treated in India. Some sixty years ago William Cobbet suggested that chesnut and ash should be grown in Kent and Sussex for hop-poles, and the way this was done was to plant them a certain distance apart, and after a time they were cut down, and from the stem or stool grew up the poles, which were cut every ten years. His experience of tea was somewhat similar to his experience of chesnut and ash-growing. The tea-plant was cut down, and from the suckers which spring up the leaves were plucked, and there was reason to believe that the roots of the tea-plant grew deeply into the ground, and that manuring would do it little good."

Our own experience is that the tap-root of the tea-plant goes down at least six or eight feet into the subsoil (we heard of its penetrating cabook and of splitting its way through the fissure of a rock), and we have seen lateral roots as thick as a man's thumb extending fully twelve feet away from the parent stem: does it not, therefore, stand to reason that a plant, whose own roots so largely open up the ground, should be one of the readiest to respond to manure, which at the first shower of rain would find its way in a liquid form along the root itself down to the very lowest depth to which the latter had penetrated, although, of course the tree is fed chiefly from the smaller rootlets. The undoubted success which attended the burying of the prunings on a small portion of our estate last year has led us this year to go to the expense of burying everything over the whole pruned acreage. The result, we confidently anticipate, will be an increase of over 100 lb. made tea per acre, which was the result secured from the first burying.

The Chairman, in answer to Mr. Seton, a Cachar planter, who said that he had found it advantageous to manure accompanied by a deep hoeing, replied that it would be an absolute impossibility for this company to manure its 7,500 acres in Assam." Mr. Albert B. Fisher (a director), said:—"I have tried it in Assam. I acknowledge the utility of manuring, but the difficulty of doing it on a large scale is very great, and the growth of weeds which springs up where the manure is used also causes very great difficulty." Of course the growth of weeds is an objection, but a very small one when the end in view is taken into consideration. The Chairman himself had at the commencement of the discussion stated that they were only producing 350 lb. per acre, but that he should not be satisfied, if he lived, unless he saw the gardens yield at least 500 lb. to the acre. We suspect he would see that and more if orders were given for manuring, though, of course, the deep, rich soil of Assam does not need assistance so much as our comparatively poor soil in Ceylon does. The following extract is interesting as showing the size to which the tea-tree will grow, and as refuting a suggestion that was put forward last year at the Dimbula Planters' Association Meeting that tea made from old plants would be lacking in flavour. The Chairman said:—

With respect to this company's experience, the shareholders were aware that we were the pioneers of tea cultivation in India. We took over some experimental gardens from the old East India Company. Those gardens were formed in consequence of a certain Mr. Bruce, who went to Assam, having discovered, or believing that he had discovered, the indigenous tea plant but which we now believe to have been the remains of old tea plantations which were planted at a time when Assam was in a much higher state of civilization than when this company entered upon the gardens. Those trees were growing in patches; they were actually trees. He had one stump sent home to him, which was as large in circumference as a hat. This company never made such good, strong, and well-flavoured tea as during the first three or four years of its working from these old forest trees, which had been growing there for probably hundreds of years, and which were subsequently cut down, and from the stumps of which grew up the young plantations from which the Assam Company made their first importation. An ordinary top-hat is about 26 inches in circumference: on Abbotsford we have measured a tea-stem 22 inches round, so that there is abundance of testimony that the tea-trees has found a congenial home in Ceylon, and that on leaving Assam it did not say, as the majority of our coolies do on leaving their *simei*, "Pōyittu vārēn" (I go and come again), but "Pōyittu nirkirēn" (I go to stay).

The Assam Company have only just ordered machinery; the reason given for the delay was that the Directors had been waiting for a perfect machine to be produced before experimenting with untried inventions They might have gone on till Doomsday pursuing this short sighted policy and waiting for what will certainly never be produced in this world, a *perfect* machine, had they not been stirred up by finding that young, ably managed companies with only one-twelfth or one-eighth of their out-put could produce leaf at a less expense per pound than the Assam Company.

In taking over the following statistics we would draw attention to the two remarkable facts that the

dividend paid per share in 1881 was 25 per cent, and that in 1862 the average price per lb. was 2s 5⅞d.

ASSAM COMPANY.

	1883.	1882.	1881.	1880.
Area under Plants. Acres	7,577	7,515	7,435	7,331

1883 ...	2,569,961 ...	1/1

From the following "Tea Statistics," also contained in the *Home and Colonial Mail*, it will be seen how surely and steadily Indian tea has been gaining ground, while China has been wavering and receding. Japan and Java too are coming to the front, proving that after all, much as some nations and traders scorn the axiom, honesty *is* the best policy:—

TEA STATISTICS.

Imports and deliveries from 1st June to 31st May, 1881-82, 1882-83 and 1883-84, with stocks on 31st May, 1882, 1883 and 1884.

Imports.

	1881-82. lb.	1882-83. lb.	1883-84. lb.
China tea ...	159,511,000	145,907,000	148,609,000
Japan tea ...	110,000	72,000	112,000
Java tea ...	1,718,000	2,656,000	3,501,000
Indian tea ...	49,455,000	56,764,000	63,035,000
Total ...	210,824,000	205,399,000	215,257,000

Deliveries.

Java tea ...	721,000	1,111,000	1,244,000
Indian tea ...	19,216,000	19,069,000	21,482,000
Total...	86,148,000	76,834,000	76,199,000

We must conclude today with the following note from the *Produce Markets' Review*:—

In an article on the decreasing trade between India and Australia, about which such sanguine expectations had been formed, the *Calcutta Englishman* says:—"The extraordinary decline in the item of tea is due to special causes. The trade has hitherto been somewhat of a speculative character; great variations might, therefore, be expected. The Australians also, it is well known, object to the system under which Indian teas are packed. They are put up in ungainly boxes and packages, such as tea dealers do not care to see displayed in their shop windows. The boxes of China tea please the eye, and attract the customers. The complaint seems sound, and it would be well did planters in this country study the æsthetics of their business. The trade, again, has been depressed during the year by the knowledge, on the part of exporters in India, that a great amount of their tea, first shipped to Australia, has been sent from that colony for sale to London, where prices happened to be ruling higher. Planters have, therefore, naturally and wisely concluded that they might as well reap the extra profit themselves."

THE CINCHONA ENTERPRIZE IN JAVA.

Translations of the annual reports for 1880 and 1881 appeared in the May number of the *Tropical Agriculturist* and that for 1882 (the latest out) is given below. Now that the railway is open to Bandoeng, the question of carriage rendered difficult by the frequent occurrence of cattle-murrain, will cease to be a subject of complaint and the labour supply is likely to be more adequate to the demands of the Government plantations. In 1880, the grafting of Ledgeriana scions on succirubra stocks was continued as it was found that the trees planted out were growing well. It was discovered subsequently, that in order to check the tendency in such trees to extreme lateral growth, it was necessary to prune away the lower branches, such branches at three to four years old, yielding an appreciable quantity of quinine. The growth of the trees was checked by a severe attack of *Helopeltis*, but neither in these reports nor in anything we have read about cinchonas in Java have we found any record of trees being killed outright by these insects. Most of the plantations were attacked and it is noted that

They also made their appearance in the cuttings and gratts at Tirtasari in the latter part of the year, but as they were immediately discovered they could be completely exterminated. Means were taken everywhere, by catching these insects, to prevent the evil as much as possible.

"As much as *possible*," for, in some years the green flies came in such multitudes that there was nothing for it but to allow them work their will, the trees recovering when they disappeared. The meteorological or other conditions which regulate the movements of these pests seem as mysterious as those which guide

the flights of butterflies in Ceylon; but it would seem that abnormal weather of any kind, especially drought, following floods or excessive rainfall is favourable to the existence of blights of every kind, "red spider" as well as "green fly." We quote what is said about "scraping" and "stripping" as modes of harvesting bark:—

Scraping was continued during 1880; but, in order to injure trees rs little as possible, the bark was only taken from two sides, whilst the other twe sides were left untouched. And, if formerly mention was made of the trees suffering a little from this process, it was now found that no difference could be observed between the trees that scraped and those that were not, although standing together. From the 60 Ledgeriana trees that were treated in this manner in 1878 for the first time, the new bark has been removed this year. In 1878, fifty kilos was obtained from these: now fifty-five kilos was cut from the stem. McIvor's method of stripping succirubra was continued, and use was made of the alang-alang to cover the trees. The Director of the Government Cinchona Gardens saw in Ceylon and at the Nilgherries that grasses among them the *Imperatum Koenigii*, were pretty generally used with great success to cover the stripped trees. After this was reported to Java, a trial was immediately made here with this grass, which is so common near the cinchona gardens, and consequently so cheap. The renewed succirubra bark of the 1879 crop fetched a price nearly one-half in excess of the best original barks, notwithstanding its unsightly appearance. This difference in price was owing to the greater quantity of quinine it contained. We need scarcely remind our readers that the "alang-alang" grass mentioned is known in Ceylon as "iluk." Here in Ceylon, it occurs occasionally. The doubling of the name shows its prevalence in Malaysia and Java.

The report for 1881 commenced with the record of a storm which destroyed 2,000 trees on Nagrak, as it was stated—

During the dry monsoon night frost was again twice experienced. In the same gardens where, in 1877, plants were killed by it, flat, in some measure basin-shaped spots on the plantation at Tjibitoeng, the trees again suffered most. A 1½ year old group of *C. succirubra*, consisting of very well developed trees, was damaged the worst: they were frosted down to the ground; but there was enough of the lower part of the stem spared to allow of sprouts to be formed on it, which are now growing vigorously. This is just what has happened to so called "frosted" coffee in Ceylon, where it has been grown in damp hollows or flats. Succirubras continued to be planted in places found unsuited for Ledgerianas, so that even in Java it is only in certain situations that Ledgerianas flourish. A succirubra plantation which appeared not to get on well was fully restored by constant digging during four months' drought, rather an expensive remedy. The insect enemy of the cinchonas was thus alluded to:—

The *helopeltis* steadily continues its ravages, and we are powerless to to combat the little insect. The catching and killing was carried on in the young plantations, but the effect is very local, and those caught are speedily replaced from the millions that live on the high trees in the older plantations.

Then comes notice of a disease which we suspect was our "gum disease," and that chemical disorganization and not a fungus was the cause:—

At Nagrak a disease appeared in the officinalis plantations which apparently must be ascribed to the destruction caused by the location of a fungus in the bark. The tops of the plants are found to die off here and there, to about 3 to 6 feet from the ground, above a place on the stem where the bark is discolored and generally swollen. The portion of the stem below and the root are perfectly sound, so that the affection is a local one, and the explanation is very probably that it is caused by a fungus, which first obtains a nidus in the bark and then extends its ravages also to the wood, until the tissue is so altered and destroyed as to render impossible the nutrition of the portion of the stem situated above the diseased place. I caused all the diseased tops to be sawn off, and after the bark was gathered from them the wood to be burnt.

In Java they quite believe in and practice artificial drying of the bark by means of furnaces. The following statement is important:—

The Ledgeriana bark cut in flakes fetched *f*6·94 to 7·48 per half kilogram. The two year old renewed Ledgeriana bark cut in flakes fetched, on the other hand, only *f*5·76 per half kilogram. The yield of quinine was lower than that of the original bark, and its separation was besides less easy, on account of the greater quantity of resinous and coloring matter. It has therefore now been resolved to leave the renewed bark of this variety until it is three years old before it is shaved off. Partial stripping has been carried on more and more largely, whilst the experiments with shaving have been continued on an extended scale. Although an opinion cannot yet be given with certainty as to the comparative value of these two methods, it is probable that in the case of *C. succirubra* partial stripping with a subsequent covering, and in those of *C. officinalis* and *C. Ledgeriana* shaving, is preferable. For covering, grasses are now exclusively employed: where alang-alang is easily procurable it has the preference, but other grasses also found on the plantations, appear to be very good for use. The covering is bound fast with indjoek string, which is very durable and is used solely for this purpose, or with ratan.

Experiments in the hybridization of the cinchonas had been carried on with success, plants being got by the fertilization of Ledgeriana with succirubra. Mr. Moens was led to the conclusion that Ledgeriana bark is ripe in the 7th to the 8th year, and that after this age the quantity of quinine does not increase. He also found that the best Ledgerianas could be recognized by external appearance apart from the necessity of analysis. All experience went to prove that the succirubra stock had no effect on the bark of the graft. This system of grafting, however, is stated to be too expensive for private plantations, and, as plenty of seed can now be got and the high-class plants selected from the nursery, there is happily no necessity for the process.

The report for 1882 commences with the complaint that this year also was without a proper east monsoon, and it seems beyond question that in the mountain regions of Java the seasons are far more distinguished for failure of rains than the hill-country of Ceylon. But the rich volcanic soil atones for climatic defects. A gardener having arrived from Holland, nurseries and grafting operations had been extended and a large new propagating-house had been erected. Experiments in open-air grafting, such as gave very good results to Mr. W. Smith of Mattakele, had not been successful in Java. On stems over two years old, failure with inoculations was uniform. Then it is stated:—

As ferule grafting had succeeded in the propagating-houses, it was also tried in the open air. Of about one hundred of these grafts only eight succeeded, whilst in the propogating-houses on an average 75 per cent are successful. Crown grafting, tried in various ways, gave very poor results, both on young and old systems. The excessive bleeding of the truncated succirubras, which in some cases lasted more than two months, hindered the union of the two wounded surfaces. The experiments, in some degree modified, are being continued. Grafting is of the greatest importance to the Government enterprise, that a plantation may be obtained consisting solely of grafts of the Ledgeriana individuals richest in quinine. In a short time moreover an abundant supply of seed of the best quality may be expected. It is not advisable for private persons however to lay out their estates in this manner alone. Grafting costs besides too much time and care, and progress is too slow. The Government cinchona enterprise, with a nursery area of about 1,000 square Rhenish feet and with a skilled *personnel*, is only in a position to produce 36,000 successful grafts per annum. A good crop of Ledgeriana seed, to which about 1,600 of the young grafts contributed gave the opportunity of meeting the demands of private

persons for seed of this variety. A large quantity of succirubra seed was also distributed, whilst the applications for seed of *C. officinalis* were few.

Where fields had been planted a second time with cinchonas, the experience was that some portions were perfectly healthy, while other patches were sickly and required constant supplying. We have again a notice of the Helopeltis plague and the story is the same: much immediate damage, checking growth, but there is no indication that a single tree was killed outright even of "the grafts." We quote what is said regarding this troublesome insect and a coogener:—

The *Helopeltis Antonii* again did much damage. Notwithstanding the greatest care, the graft plantation at Tirtasari had to endure a severe attack, but by the end of the year the trees had to a large extent recovered. On the establishment of the Kendeng-Patoeha, where the *Helopeltis* has not yet shown itself, another insect of the order of the Hemiptera, a small, light green colored insect, has lately appeared in large numbers and is beginning to injure the officinalis plants in the same manner as the *Helopeltis* does. Hitherto it has not been proved that this hemipter lays its eggs in the cinchona plants as does the *Helopeltis*, and young, immature insects have not yet been met with. The disease in *C. officinalis*, from which the top dies off, and which was spoken of in the previous year's report, again made its appearance, but in much less measure than in 1881, so that it caused little damage.

The disease alluded to as occurring in *C. officinalis*, seems to be identical with that which, without either insect or fungal origin, developed so badly in Ceylon in 1882. But here it attacked all the cinchonas and not merely *C. officinalis*. There were not sufficient labourers in 1882 for harvesting the bark. We notice that while the highest price obtained in Amsterdam per half-kilo for Ledgeriana bark was 670c. some officinalis bark sold for 410c., while succirubra realized as a maximum 253c. In regard to the shaving process and the value of renewed bark three years old, we quote as follows:—

A portion of the original Ledgeriana plantation, which was shaved for the first time in 1879, was once more subjected to this operation. The renewed bark, which was now three years old, had acquired the very high quinine yield of 9·26 per cent, whilst the yield of the shavings of the original bark was only 7·8 per cent. The plantations of the original trees, 8½ bouw more or less, had once more to be pruned and some trees removed. In this manner 9,073 kilos were obtained, or 1,067·5 kilo per bouw. By the pruning of the young Ledgeriana plantations also a considerable quantity of bark was obtained, which, possessing as it does an average of more than 2 per cent of quinine, is suited for the preparation of quinine sulphate. The grafts at the Tirtasari plantation also contributed to the harvest, by the bark of the pruned branches. A large quantity of succirubra stem bark, 1st sort, was obtained solely by the partial stripping of the stemps. The shaving of these old succirubra was found not to be advantageous, as the tree being left uncovered the bark renewed in insufficient quantity. As a rule a light covering for the shaved trees is necessary in the case of all varieties, to hasten the renewal of the bark and increase its quantity. Owing to the depression in coffee, the planting of cinchonas by planters was increasing largely, but "experimental cultivations" intended to induce the natives to engage in the pursuit had failed of their object. The Malays of Java are just as conservative as the Sinhalese of Ceylon. The former obtain such good returns generally from their paddy-fields, grain in the dry season and fish in the wet, that it is natural they should hesitate to turn aside to a new culture. When we were in Java, much was expected by the Forest Department from growing cinchonas, especially the large-leaved succirubras as shelter for ordinary forest trees. But the weeds being allowed to grow up, the cinchonas got choked and scarcely grew at all. Evidently, therefore, weeds do not help but hinder cinchonas. Mr. Moens stated:—

By Government order No. 26 of 27th November 1882, permission was given to offer for public sale 2,000 Ledgeriana grafts per annum at a minimum price of ten guilders the graft. The principal object of this resolution was to give private planters the opportunity of obtaining, for artificial propogation and seed-bearing plants derived from mother trees whose yield was known with certainty. For this sale grafts were chosen of the mother trees, 89 yielding 11 per cent and 73 yielding 10·6 per cent of quinine. The value of the Dutch guelder closely approaches that of the Indian rupee. Hybrid cinchonas, including those obtained from British Sikkim, were making "sturdy growth." The result of chemical analyses showed 9 per cent of quinine as the average for Ledgerianas in the Government Gardens while picked types reached so high as 12·3 per cent. Such excellent types were not confined to the Government Gardens but existed on private plantations also.

What Mr. Moens says respecting hybrids is so important to planters that we copy the passage:—

Among the plants raised from seed of *C. Ledgeriana* now-more or less of individuals are met with, which by their free growth and large broad leaf approach *C. succirubra*, and are apparently hybrids of the two varieties mentioned. The alkaloid determinations 25-38 are of bark cut from such hybrids, and it will be seen by these that the quinine yield of these trees can now and then be very high. Their cultivation should be very profitable, as, when grown from seed, they return true to type, whilst they grow more easily and rapidly than *C. Ledgeriana* and produce more bark in the same time than the latter. A little seed of the best among them has been sown, that this may be proved. As hybrids between succirubra and Ledgeriana as well as between succirubra and officinalis will grow in situations where Ledgeriana and officinalis die out or only linger in a sickly state, we have here another proof of the wisdom of paying attention to the culture of good hybrids. By seedlings from such trees returning true to type, we understand Mr. Moens to mean that the hybrids mainly reproduce their kind. Of course, plants of pure succirubra, pure Ledgeriana and pure officinalis will occur in the nurseries. It was once more proved that the root-bark of C. officinalis was very rich in quinine, but Ceylon experience has been attended with much uncertainty and disappointment in regard to prices paid for root-bark. In Java, as in Ceylon, the amount of alkaloids in cinchonas was found to increase in proportion to altitudes, while renewed bark gave inferior results to natural if not left on the tree for three years. Some experiments in Ceylon led at one time to the belief that trees could be advantageously shaved twice a year. Having to wait three years detracts much from the profit of the pursuit. The Dimbula experiments seemed to favour stripping in preference to shaving, but it does not seem as if results were in all situations and in all seasons similar. What seems certain is, that if the bark is rich in quinine, the manufacturers will pay high prices whether for flakes or quills; but the druggists will always give fancy prices for very fine and very long succirubra quills.

REPORT ON THE GOVERNMENT CINCHONA ENTERPRISE IN JAVA FOR THE YEAR 1882.

BY J. C. BERNELOT MOENS.

1.—*Weather.*—As will be seen by the rainfall returns for Tjinjiroean, Kawah-Tjiwidei and Soekawana appended to this report, 1882 was also a year without a proper east monsoon. The months of August and September were as usual marked by fewer rainy days, while December, quite abnormally, also showed about 18 dry days.

2.—*Increase.*—At the end of December last the number of plants in the open was 2,099,400. Of these 85,000 were grafts and cuttings of *C. Ledgeriana* and 609,900 Ledgeriana seed plants. In the nursery beds there were also 820,700 plants of this variety, of which 16,750 were cuttings and grafts. A number of these can be planted out during the early months of 1883. The number of plants of *C. succirubra* in the open was augmented by 48,900,

that of *C. officinalis* by 17,000. In the case of these varieties also the dry weather in December hindered the planting out, so that at the end of the year the greater portion of the plants intended for that purpose remained in the beds. About 80,000 trees of the inferior varieties, or those that for some other reason had to be removed, were rooted out. The plants raised from the consignment of seed received from Hr. Schuhkraft in 1881 were not yet in a fit condition for planting out. They have not yet developed sufficiently for a definite idea to be formed of the varieties to which they belong. From the Nilgiris seed was received of the "hybrid"—now generally called *C. robusta*. From the Director of the Botanic Garden in Jamaica also seed was received of a variety of calisaya and of a hybrid of a good quality from the cinchona gardens there. Propagation by grafts was continued, and the number of successful grafts has increased greatly since the services of G. Toekamp Lammers, the gardener sent from the Netherlands, have been available. A very large propagating-house, erected solely for the making of grafts, was built in the first half of the year at Tjinjiroean, and was ready and at the service of the gardener in July. To the latter was also entrusted the making of experiments with grafts in the open air, but results obtained by him in this manner have been small as yet. Of eighty-eight inoculations placed on thirty young succirubras in May, only ten, on six very young trees, succeeded well, and these are now growing vigorously. On older stems, those over two years old, the inoculations did not succeed. As ferule grafting had succeeded in the propagating-houses, it was also tried in the open air. Of about one hundred of these grafts only eight succeeded, whilst in the propagating-houses on an average 75 per cent are successful. Crown grafting, tried in various ways, gave very poor results, both on young and old stems. The excessive bleeding of the truncated succirubras, which in some cases lasted more than two months, hindered the union of the two wounded surfaces. The experiments, in some degree modified, are being continued. Grafting is of the greatest importance to the Government enterprise, that a plantation may be obtained consisting solely of grafts of the Ledgeriana individuals richest in quinine. In a short time moreover an abundant supply of seed of the best quality may be expected. It is not advisable for private persons however to lay out their estates in this manner alone. Grafting costs besides too much time and care, and progress is too slow. The Government cinchona enterprise, with a nursery area of about 1,000 square Rhenish feet and with a skilled *personnel*, is only in a position to produce 36,000 successful grafts per annum. A good crop of Ledgeriana seed, to which about 1,600 of the young grafts contributed, gave the opportunity of meeting the demands of private persons for seed of this variety. A large quantity of succirubra seed was also distributed, whilst the applications for seed of *C. officinalis* were few.

3.—*Extension; Upkeep.*—On the establishment of Kendeng Patoeha twelve more bouws of jungle were opened, whilst at Tirtasari all the forest previously felled has been cleared for planting. The necessary space was also obtained by the uprooting of calisaya plants. Careful upkeep—the keeping clean and draining of the gardens—was pursued, as far as the necessary forces permitted. The growth of trees on places that have been planted for the second time is irregular. Some of these fields are exceedingly healthy, quite as good as those opened in virgin soil, while others look sickly and need constant supplying. The measurements mentioned in previous annual reports were resumed in the same month of 1882. The crown circumference was however no longer measured, as these trees have been pruned, and the figure obtained therefore would not correspond with the previous one. In the Ledgeriana plantation at Tjiheureum the mean height was now 3·14 meter, the mean stem circumference 0·22 meter. The greatest height was 3·70 meter, the greatest stem circumference 0·27 meter. The grafts at Tirtasari, which are now three years old, had a mean height of 2·12 meter, with a mean stem circumference of 0·19 meter. The greatest height here was 2·78 meter, the greatest stem circumference 0·225 meter. Among the cuttings of the same age the mean height was 1·76 meter, the mean stem circumference 0·145 meter, whilst the maxima were : height 2·75 meter and stem circumference 0·205. The *Helopeltis Antonii* again did much damage. Notwithstanding the greatest care, the graft plantation at Tirtasari had to endure a severe attack, but by the end of the year the trees had to a large extent recovered. On the establishment of Kendeng-Patoeha, where the *Helopeltis* has not yet shown itself, another insect of the order of the Hemiptera, a small, light green colored insect, has lately appeared in large numbers and is beginning to injure the officinalis plants in the same manner as the *Helopeltis* does. Hitherto it has not been proved that this hemipter lays its eggs in the cinchona plant as does the *Helopeltis*, and young, immature insects have not yet been met with. The disease in *C. officinalis*, from which the top dies off, and which was spoken of in the previous year's report, again made its appearance, but in much less measure than in 1881, so that it caused little damage.

4.—*Harvesting of Cinchona.*—The crop of 1882 amounted to 126,595 kilogr., of which 125,215 kil. were destined for sale in Europe, and 1,380 kil. for the medical service in [Netherlands] India. The quantity would have been greater, had it not been that during a portion of the year too few laborers were available. Gardens which needed thinning had on this account to be left without pruning. The drying of this large quantity was sometimes very difficult, on account of the continuous rainy weather. The drying-room at Nagrak did good service, but will have to be enlarged in 1883. The drying furnace at Tjinjiroean is nearly completed, and next year one will have to be built at Rioen-Goenoeng as well. The transport of the packed bales did not proceed as rapidly as could have been wished, on account of a lack of means of transport, so that, at the end of the year, about 350 bales more had to be dispatched to Tjicao. An improvement in this matter can only be expected when the railway is opened to Bandoeng. The cinchona bark of the 1881 crop was sold at Amsterdam on 23rd May. The following prices per half kilogram were obtained:—

C. succirubra	...	...	...	88c	to 253c
C. Calisaya javanica			...	55c	„ 200c
C. „ *Schuhkraft*			...	47c	„ 164c
C. Ledgeriana	...	...	...	78c	„ 670c
C. Haskarliana	...	...	...	60c	„ 180c
C. officinalis	...	...	...	264c	„ 410c
C. lancifolia	...	...	...	135c	„ 175c

The average price of the whole consignment was *f*1·54⁵ per half kilo. A consignment of 2,371·5 kil. succirubra bark, which was originally intended for the preparation of quinetum, was afterwards also sent to the Netherlands for sale, and was sold at Amsterdam on 11th October. The prices per half kilo varied from *f*0·75 to *f*2·20. The average price of the whole consignment was *f*1·66⁵ per half kilo. The whole crop of 1881 realized a total of *f*242,607·20, or *f*218,441·75 nett. During the auction in May the price of sulphate of quinine was *f*170 per kilo, with a downward tendency. A portion of the original Ledgeriana plantation, which was shaved for the first time in 1879, was once more subjected to this operation. The renewed bark, which was now three years old, had acquired the very high quinine yield of 9·26 per cent, whilst the yield of the shavings of the original bark was only 7·8 per cent. The plantations of the original trees, 8½ bouw more or less, had once more to be pruned and some trees removed. In this manner 9,073 kilos were obtained, or 1,067·5 kilo per bouw. By the pruning of the young Ledgeriana plantations also a considerable quantity of bark was obtained, which, possessing as it does an average of more than 2 per cent of quinine, is suited for the preparation of quinine sulphate. The grafts at the Tirtasari plantation also contributed to the harvest, by the bark of the pruned branches. A large quantity of succirubra stem bark, 1st sort, was obtained solely by the partial stripping of the stems. The shaving of these old succirubras was found not to be advantageous, as the tree being left uncovered the bark renewed in insufficient quantity. As a rule a light covering for the shaved trees is necessary in the case of all varieties, to hasten the renewal of the bark and increase its quantity.

5.—*Staff; Expenses.*—The staff was augmented during 1882 by a gardener, G. Toekamp Lammers, who begun his work at Tjinjiroean in May. The grafting and bedding of plants at that establishment is committed entirely to him. The fixed native staff at the end of December consisted

of 1 cinchona mantri, 1 carpenter, packing-house mandoer, and 218 boedjangs. During a portion of the year the supply of labor was insufficient. The cost of the enterprise was:—

Salaries of the European staff	...	f31,208·33
„ „ „ native „	...	24,060·71
Wages of day laborers	... ...	11,473·505
Stationery	... ...	360·00
Travelling and halting expenses	...	2,563·12
Making and repair of implements	...	399·73
Transport and packing of cinchona		5,407·15
„ of money and materials		490·17
Materials for propagating houses, drying furnaces and sheds	... ...	3,461·73
Requisites for the laboratory	...	297·00
Servants for „ „	...	180·00
Total	...	79,901·445

This amount exceeds the estimate in the budget of 1882 by f5,141·445, which is chiefly due to the larger crop.

6.—*Distribution of Cinchona.*—The desire to plant cinchona is spreading more and more among the European planters. On account of the low prices for coffee, cinchona is beginning to be planted on most of the coffee estates, for which these are generally suited. By Government order No. 16 of 8th April 1882 it was enacted that the heads of the provincial Governments should no longer be required to report half-yearly on the condition of the experimental cultivations in their residencies, but that in future they should, in the report which they have to send in yearly, mention what had been done by them towards the promotion of cinchona culture. On account of the great extension of cinchona cultivation by private persons, these experimental cultivations have entirely lost their value to the population. They have been of very little use, as the people have nowhere been induced by them to plant cinchona on their own account. The foresters in the residencies of Pekalongan, Bagelen, Kedoe, Samarang and Japara have used cinchona as an alternate plant in laying out forest land. The Director of the Government Cinchona Enterprise was ordered to enquire into the condition of these plantations, and this he did in the months of October and November. This opinion, given in a separate report, was not very favorable. On most places too large extents had been planted, so that later on the means were wanting to keep them in good condition. The plants were then choked by the bad varieties of weeds which prevail in these unwooded places, and have scarcely grown at all, so that the aim was not reached. Where the upkeep of the plants could be well attended to *C. succirubra* appeared well suited for the purpose, but the use of other varieties of cinchona must be abandoned. By Government order No. 26 of 27th November 1882, permission was given to offer for public sale 2,000 Ledgeriana grafts per annum at a minimum price of ten guilders the graft. The principal object of this resolution was to give private planters the opportunity of obtaining, for artificial propagation and seed-bearing, plants derived from mother trees whose yield was known with certainty. For this sale grafts were chosen of the mother trees, 89 yielding 11 per cent and 73 yielding 10·6 per cent of quinine.

7.—*Information regarding the Varieties of Cinchona Cultivated in Java.*—The only tree which has yet blossomed of the thirteen raised from the seed obtained in 1872 from Hr. Schuhkraft appeared not to agree entirely in blossom with the typical Ledgerianas. The blossoms were indeed pendant, but light rose red in color. It is just possible that this form approaches more nearly to the *C. Calisaya* of Weddell, which also agrees with the statements of Howard, that the true Calisaya bark of Bolivia always contained cinchonidine, which is found in considerable quantity in the bark of these trees also. The plants of *C. Trianæ* (*C. Pitayensis*) have been divided among different plantations, from 3,000 to 6,000 feet above sea-level, in order to ascertain which climate is best suited for them. As yet they have grown very quickly and every where equally well. The hybrids planted in the open at Tjinjirocan are growing very sturdily. In habit they appear as yet to hold a mean between the two varieties from which they are sprung. The hybrid from British Sikkim also, which is planted in the same place, is making a good show in the climate of this garden.

8.—*Chemical Analyses.*—In the appended statement B the results are given of the alkaloid determinations which called for any special remarks. 1-21 are alkaloid determinations of four year old descendants of *C. Ledgeriana*, of very typical aspect. They possessed, in common with the latter, a very high yield of quinine. The analyses 7 and 16 relate to bark cut from ten trees which had not been picked out, but taken as they come to hand one after another on a terrace. The figure of 9 per cent quinine, therefore, stands more for the average of the stem bark from this plantation, whilst the quinine yield of picked types reached so high as 12·3 per cent. These excellent types were not confined to the Government gardens, but are also not infrequent in private plantations, as the analyses 18-24 testify. Among the plants raised from seed of *C. Ledgeriana*, now more or less of individuals are met with, which by their free growth and large broad leaf approach *C. succirubra*, and are apparently hybrids of the two varieties mentioned. The alkaloid determinations 25-38 are of bark cut from such hybrids, and it will be seen by these that the quinine yield of these trees can now and then be very high. Their cultivation should be very profitable, as, when grown from seed, they return true to type, whilst they grow more easily and rapidly than *C. Ledgeriana* and produce more bark in the same time than the latter. A little seed of the best among them has been sown, that this may be proved. It was evident, from previous analyses, that that the bark of *C. Ledgeriana* renewed after shaving had not, after one and even after two years, returned to the original quinine yield, in the case of trees fifteen years of age. For this reason, in the case of a large number of trees, three years was allowed for the renewed bark to recuperate, and now the analysis 40 proves that the renewed shaving contained 9·26 per cent quinine, or nearly 1½ per cent more than the original, twelve year old bark, which, according to a specimen analysed in 1879 then contained 7·8 per cent quinine. The branch and twig bark obtained by the pruning of the young Ledgeriana gardens appears to give a very good material for the preparation of quinine, as analyses 45-54 prove. The quinine yield varied in different lots from 1·45 to 4·38 per cent. No. 50 is an analysis of this same assortment of bark, obtained by the pruning of the one to three year old gardens in the graft plantation at Tirtasari. Besides these, analyses 41-44, 55-57 and 59 also refer to grafted trees. In order to give a better idea, I have here arranged these analyses in another form :—

1.—*C. Ledgeriana*, grafted on *C. Josephiana*.

2.—„ „ „ „ *succirubra*. The grafts were taken from the mother tree 89. Bark of 21 two year old plants.

3.—*C. Ledgeriana*, grafted on *C. succirubra*. The grafts were taken from trees whose leaves are purple on the under side. The bark was from ten trees, 2½ years old.

4.—*C. Ledgeriana*, grafted on *C. succirubra*. Bark taken from 9 three year old trees of ordinary type.

Later on, an analysis was made of bark taken from young trees, produced by grafting Ledgeriana slips from the mother tree No. 23 on succirubra stems. From this was obtained, for the Ledgeriana bark, 7·37 per cent quinine, no cinchonidine, and 1·14 per cent cinchonine and amorphous alkaloid. The relatively high proportion of cinchonidine found in 3 and 4 appeared for a moment to justify the fear, that some influence was possibly exerted by the succirubra stem on the Ledgeriana graft. The quinine yield of the succirubra stems was at the same time somewhat higher than usual, so that this would point to a

mutual action of gratt and under-stem. The analyses of the bark of those trees produced from grafts of 89 and 23, however, remove this fear. In neither was a trace of cinchonidine met with. The presence of this alkaloid therefore in 3 and 4 must be explained by the fact, that in these cases grafts from cinchonidine-yielding mother trees had been used. In future grafts will be taken only from trees in whose bark there is no cinchonidine, and preferably from the tree 23, of which there is already a large planting, and the seed of which gives a constant supply of plants distinguished by a very high quinine yield. By the analysis of officinalis bark it was once more proved that the root bark of this variety is very rich in quinine. The analysis 62 is of the bark of a tree grown at Lembang, about 14 years old, which had developed slowly. the alkaloid yield is however very high. A typical *C. officinalis, var. angustifolia*, analysis 63, also once more demonstrated the high quinine yield which, in the case of this variety, Broughton was the first to discover. The one year old renewed bark of the officinalis hybrid, analysis 64, which in its original bark contained 10 per cent of alkaloid, of which 2 per cent was quinine and 6·9 per cent cinchonidine, now gave 2·8 per cent quinine and 1·8 per cent cinchonidine. The bark of the *C. cordifolia* trees at Rioen Goenoeng, grown at 5,000 Rhenish feet, contained an amount of quinine which was notably higher than what has hitherto been met with in bark of this variety.

BANDONG, 28th Feb. 1883.

(*) Sockawana, a private cinchona estate, lies on the Tangkoeban Prahoe, 1·5 kilometer from the Government estate Nagrak and 30 meters lower than the residence of the observer there.

PINKOS TUBERS.

Under the name "Pinkos-knollen," a very hard red woody substance has lately been introduced into the Vienna market, probably from Australia, which is found to be almost as valuable for turning purposes as ivory. Dr. Franz von Höhnel has subjected this substance to careful examination, and has determined, from the following characters, that it is the product of a coniferous tree belonging to the family Araucarieæ:—1. The absence of true vessels. 2. The absence of resin passages. 3. The extremely thin-walled medullary rays, consisting of a single row of cells, comparatively large, and placed in bulgings of the tracheids. 4. The remarkable pits which indicate the tracheids on the borders of the medullary rays. 5. The large bordered pits of the tracheids, which meet from opposite sides, usually placed in two rows, and then nearly polygonal. 6. The sclerenchymatous pith, from 4 to 5 millimetres wide. The so-called "tubers" are turnip-shaped, 15-40 centimetres long and 7-16 broad: broad and apparently broken off at one end, running out into a point at the other end. The transverse section shows a sclerenchymatous pith, 4-5 millimetres wide, surrounded by a number of very narrow annual rings, the older of which are concentric, the outer ones strongly excentric. They are usually covered by rotten wood and soil, and are probably gigantic knots which have fallen out of decaying and mouldering trunks in the primeval forest. Of the genera of Araucarieæ they must be derived from either *Araucaria* or *Dammara*, and very probably from *Araucaria Bidwillii*, the "bunya-bunya pine," a native of New South Wales.—*Pharmaceutical Journal.*

AGRICULTURE ON THE CONTINENT OF EUROPE.

(Special Letter.)

PARIS, June 21st.

Except for the extending ravages of the phylloxera, French farmers would not have much to complain of this season so far. The grass crop is short and light, but hopes are entertained that the aftermath may turn out well. In any case intercalary crops are being taken. Cereals are well cared, and the filling promises fairly. The rains, warm and refreshing, are telling favorably on roots. The Beet crop will be a fair average, but the area of land under it will be less than last year. The sugar industry appears to be in a state of confusion; the manufacturers are not opposed to levying the fiscal dues on the roots rather than on the juice, but they demand the government to accord them a bounty, in order to hold the market against the German and Russian producers. In the end they may succeed as have the ship-builders. No farmer complains respecting the custom's dues on live stock being more than doubled; no augmentation will take place respecting grain, but that on flour will be increased. France is free to do as she pleases to protect her interests against the foreigner; only when the latter does the same she ought not to lecture him on free trade.

French agriculture is making rapid strides; it would walk with something like seven-league boots, did the farmers possess any rational system of banking accommodation. An agriculturist is not viewed by the Bank of France as a trader, hence, his paper is refused commercial accommodation. There are roundabout ways of coming to the rescue, but they are too dilatory, too uncertain, and too costly.

The Italian farmers are a model in this way; they form in each canton a mutual guarantee for one another, and that arranged, the popular banks immediately advance the funds, and at a rate of interest not at all of a hampering character. Temporary loans to farmers are useless if not for eighteen months; longer, for permanent improvements. The French farmer must apply to usurers if he has no friends; he can of course mortgage his holding, generally his own property, but the law expenses alone would amount to 10 per cent—a two years interest at 5 per cent. Such loans ought not to be either more expensive or more difficult to negotiate than ordinary commercial paper.

Salt is a commodity, next to a necessity, for French farmers; yet it is so heavily taxed, surrounded with so many irritating conditions, as to limit its employ. You cannot cart a barrel of sea water to your house without permission of the authorities. You would be suspected of wanting to cheat the revenue perhaps by manufacturing your own salt. The tax brings in over three millions of francs annually to the exchequer; better reduce that and make up the deficiency on drink licenses. Mixed with lime salt is beneficial for all crops. It is generally applied at the rate of 3 to 4 cwt. per acre, and is most efficacious, according to Boussingault, when mixed with two-thirds of its weight of lime or marl. Salt exercises a most favourable influence on the formation of the ear of wheat, barley and oats, and adds to the weight of the grain itself. In the case of potatoes, the action is marked, the soda replacing the potash in that plant, but it is in colza that salt tells with most benefit. For feeding mangels salt is excellent, but it is detrimental when beet is cultivated for sugar. It was Davy who first directed attention to the value of salt in the agricultural point of view. It augments the appetite of stock and enables the latter to consume acid or inferior herbage. The famous *prés salés* sheep that command the highest price with the butcher, are fed on the salt marshes of Lower Normandy and the coast of Charente-Inférieure. Mixed with guano and urine salt prevents the escape of ammoniacal fumes. M. Velter concluded the ultimate action of salt was to convert organic matters into nitrate of soda. In any case before employing salt, the nature of the soil ought to be carefully studied.

M. Pasteur hesitates to give his experiments respecting inoculation against hydrophobia, with virus of rabies itself specially modified as definite, till a government commission report on same, which it will do in the course of a few months. At present Scientists seem to be concentrating their attention on microbes, bacteria, bacelli and

kindred parasites, as the causes of all contagious maladies in the animal kingdom. So far as Pasteur has operated for the *Charbon*, that is a success beyond yea or nay; the only point farmers differ about is the duration of the Anti-vaccine preventive. The foot and mouth disease is being well studied at the Alfort Veterinary College, and M. Bouley may be able in the autumn to make known the result of his inquiries conducted on the Pasteur lines.

The Agricultural Budget will be wickedly defended this year against further reductions. It is a strange fatality that agriculture is ever the last to benefit by remission of imposts, the first to be promised all ameliorations, and the earliest to be struck with fresh charges the moment the nation wants money. No wonder farmers are ever discontented in France: perhaps the history can be paralleled elsewhere. Only think that the subventions paid to the theatres are three times greater than the amount voted for agriculture, the grant allowed to the National Opera alone is more than double the amount voted for regional Farm Shows and Agricultural Societies.

What are called *Fruitières* or co-operative cheese farming is about being applied to butter. This will enable the associated farmers to have a uniform brand for a common product, which, being recognised as sound and unadulterated, will secure them collectively a more remunerative price. Why ought not the principle of co-operation to be carried farther, so as to lessen cost of production? There is a great future in the question.

France possesses some millions of acres of hunes or loosely-bound sandy soils. Genet or broom is the plant to which recourse is had as the ameliorative agent. The genet is cut regularly, and the branches allowed to decompose in the furrows, where they augment the layer of humus by their decomposition. In Belgium genet enters into a three crop rotation on looso sandy soils. The latter receive some manure, are sown with oats, clover and genet; the oats pay merely the expenses. This rotation in the course of some years gives a "skin" to the soil. In the Cerennes, sheep are fed in summer on the young branches of the genet, and in winter on its dried leaves; in Spain when the shrub attains 30 feet high it is cut down, the land broken up and sown with maize or Turkey wheat; in the Alps, genet is employed as litter; across the Alps, at Pisa, it is steeped like flax or hemp and made into coarse cordage. Ordinarily it is sown with oats after the latter is harrowed in, 12 lb. of seed to acre scattered and left bare. It gives three cuttings in the season, and is succeeded after three years by clover, oats or buck wheat.

VEGETABLE PRODUCTS OF LOANDA.

Consul Cohen, reporting on the products of Loanda, states that the cultivation—or, more correctly, the collection—of ground-nuts (Arachis hypogæa), which had for a few years back dwindled down to a fraction, has again revived, and might, if properly attended to, form one of the most valuable staples of the colony, notwithstanding its very inferior quality when compared to the produce of other countries. The reason is obvious. It can hardly be said that this valuable plant is cultivated in this colony, except in some very rare and few localities. It is merely collected from the wild plant by women and children. The plant, never improved by careful cultivation, has never yielded good nuts, which would certainly be the case in the singularly rich soil of this country if it were carefully planted from selected forms. The natives of the interior, from their habits of indolence and indifference, only cultivate the Mandioca plant and the Sugar-cane, but generally to supply their immediate wants. Many important and extensive plantations have been made of the Sugar-cane, but almost exclusively for the manufacture and distillation of rum, which is preferred by the natives, and commands a higher price than the spirit usually imported from Hamburgh under the name of white rum.

The manufacture of sugar in this colony has never been thought of, notwithstanding the facilities for cultivation of the cane, and the immense interest that would certainly be derived from an outlay of capital for that purpose.

The palm oil, which has now become one of the most important staples of the colony, is collected from the fruit or kernel of the Palm (Elæis guineensis), which grows wild throughout this province. Notwithstanding the many applications, and the utility of its production, it is never cultivated by the natives; they simply collect what the wild plant yields, and never for a moment think of benefiting the plant or tree. The yield in itself is enormous; each bunch or spadix will yield from 500 to 1,000 kernels [fruits], or "dendems," as the natives call them. Then, instead of improving this plant, the natives destroy it by extracting from the tree the juice or sap of which they manufacture one of their favourite drinks.

The Caoutchouc, or Indiarubber, grows wild and in abundance throughout the interior. If it were properly or prudently attended to, the produce of rubber would in a very few years be immense; but the natives have in many places reacted the fable of the goose with the golden egg, by destroying the tree in their greed of obtaining a larger supply of liquid, which has almost exterminated the tree in many places.

Cotton has not attained the cultivation or attention that it was anticipated and hoped it would receive; but it has been cultivated almost exclusively by Europeans who introduced it, which accounts for its having already supplanted the ground-nuts in value exported, and would become still more important and valuable if the pickers were taught to collect with more care and attention to cleanliness, which would greatly enhance in value in the European market.

Coffee continues to be the grand staple of the colony, and would certainly increase in value if the Coffee of certain districts were fairly and impartially compared with the best Coffee in the European markets; but, unfortunately for the interests of the Colony, the commercial body —or, rather, the metropolitan or home Government—has not taken any real interest in the matter, and never even thought of having it presented or compared at the great Coffee fair held last year. While Coffee from every part of the world was examined, compared, and tasted, not even a sample was shown, or a word said about the Coffee of Angola. Some districts of this province produce a very superior quality, which commands preference in a general market.

Another article that has but very recently been brought to the market with a promising future is the Tobacco of this colony. It has been known for many years growing wild in the interior, and used only as snuff by the natives; but in 1877 an active and enterprising merchant of this place, attracted by the superior quality of the leaf, established a manufactory of cigars and smoking tobacco in this city, and, owing alone to his untiring activity, wading through all impediments and endless obstructions, has succeeded in improving the natural article, and produced a smoking Tobacco which has become very popular throughout the province, selling at about 2s. 4d. per lb., besides cigars and cigarettes. There are four distinct qualities of Tobacco in the province. The first quality in every respect is the Ambacca, being equal, if not superior, to the Havanah, especially for cigars, the leaf being very large and very fine. It is highly aromatic and mild, never causing salivation. When collected with more care, and better known in the manufacturing world, it will be much sought after. The Dande, the second quality, much resembles the Virginia, and in many samples is more aromatic. The Quanza, or third quality, closely resembles the Turkish tobacco, lightly aromatic, and at the same time very mild, and therefore well adapted for cigarettes. Then the Congo, or fourth quality, is a mixture of two qualities; one very similar to good Kentucky, and the other the Dutch tobacco; but as it comes mostly from the interior, and is conducted with very little care or attention, it is not improved by the handling it now gets.

The natives smoke the leaves of a plant they call Liamba (Cannabis sativa). It is highly narcotic and stupefying, the inveterate smoker becoming idiotic and useless in a very few years. Its action is much more violent than that of Opium. Many Europeans have been addicted to its use, attracted by its stimulating or inebriating qualities. —*Gardeners' Chronicle.*

WOOD SOOT AS MANURE.—Soot obtained from a wood fire, mixed with boiling water and allowed to cool, forms an excellent liquid manure for roses. Its effects in promoting the health and strengthening the growth of flowers are extraordinary; coal soot is still more powerful.—*Leader.*

TEA MANUFACTURE AND CULTIVATION.

The *Indigo and Tea Planters' Gazette*, in its issue of July 1st, has a very sensible article upon 'Tea Withering.' It points out the mistaken economy of providing too little withering room, for, as the writer says, "if it is taken into consideration that imperfect withering gives imperfect fermentation, and consequently a deficient liquor, it must be conceded at any rate that it has very largely to do with the making of good tea, in fact, that good tea cannot be made without good withering." This we endorse with all due emphasis, for the best of rollers will break up, and the most perfect of driers will fail to make good tea of under or over-withered leaf. The 'kid-glove' standard is the safest one to follow, and to obtain it room should be provided sufficient for the spreading of the crop one leaf thick in wet weather and not more than one inch thick in dry. Should an unusually heavy flush occur in the rainy season the leaves must be tossed over two or three times during the night, but the less the leaf is handled or moved once it has left the tree the better. Every touch destroys some of the bloom, and every bruise produces discoloration both in the made leaf and in the outturn of the infusion. To ensure the withering leaf receiving the softest possible treatment we would recommend the use of some sort of canvas or cloth for the trays in preference to bamboo or wire-mesh. We cannot agree with this writer when he says: "It is almost impossible to get perfect withering, as naturally the young and succulent leaf withers much more quickly than the larger 2nd and 3rd leaves." It is just because the bud is more succulent, and because it presents a much smaller surface to the air, that it takes proportionately longer to wither, and so all the leaves small and great (not counting *bhanji* ones) are practically ready at the same time. The practice of picking the flush in wet weather *below* the eye of the third leaf instead of above as in the dry season, we have found to answer well in assisting the withering. All three leaves being on one stalk they are not so liable to stick together and retain the moisture as separate leaves would, and so the leave wither more uniformly; but there is no doubt in our minds as to the expediency of picking only the two-and-a-half leaves in dry weather, for an additional eye is left on the tree, *and the succeeding flush comes on much faster*, the difference being between 7 or 8 days and 14. The writer in the *Indigo Gazette* seems to have got a little mixed at one point, where he says that "the aim of every good tea-maker should be to get the larger leaves withered sufficiently to roll well, and yet not get the buds withered to a cinder." His mind had evidently suddenly gone off at a tangent to the drying process. He wisely recommends that the withering trays should, in a well-lighted store, be placed not more than 4 inches apart. This distance is quite sufficient for the free passage of light and air, and, if found to be too close for wet weather, the intermediate trays could be removed, and a height of 8 inches between each tray be given.

Of course in rainy weather artificial heat must sometimes be resorted to to work off the accumulated leaf, but it is quite a mistake to suppose that good tea cannot be made unless the normal temperature of the store or factory be 150° in the shade. We have heard of some places where the coolies are accustomed to faint off two or three at a time, and where the manager loses a pound of flesh a day in his hurried journey from one door to the other. On Abbotsford (it is the only estate we feel at liberty to speak of freely) the store is always kept as cool as the bungalow, one or more doors being usually open (and all (visitors welcome), and yet the average price obtained for the whole outturn of 1883 was over 1s 3d per lb.

We close with the following letter which has reached us, and our answer to it:—

Dear Sir,—The reports which you publish from the superintendent of Abbotsford contain much useful information about the cultivation and production of tea in Ceylon, which must make them greatly interesting to all concerned. Would you please complement the information, so far given, by stating what average number of trees there are per acre, and at what distances they are now and planted? TEA PLANTER.

Our answer is that when we commenced planting tea on Abbotsford we naturally took into consideration the great altitude above sea, and concluded that our bushes would never assume the luxurious growth of lower altitudes: we consequently planted 3 feet × 4 feet apart (giving 3,630 trees to the acre). But we have been pleasingly undeceived as to luxuriance of growth, and in future we would not line anything closer than 4 feet × 4 feet (2,722 to the acre). We can show separate bushes, pruned, 10 and 12 feet in diameter, and our unpruned trees from 20 to 28 feet in diameter show what tea can do in Ceylon even at 6,000 feet above sea. Of course, we have vacancies, but including the destructive effects of the dying *symplochos* stump they do not amount to more than 3 per cent of the whole acreage.

NOTES ON CEYLON KAPOK.

(From a Correspondent at Galle.)

The attention of the Ceylon public was first directed to this product as an article of export by the appearance of Mr. A. M. Ferguson's letter in the *Observer*, in which he pointed out that the so-called kapok of Java, which was largely used for stuffing purposes in Australia, was identical with the silk cotton of Ceylon. The first shipment was made from Galle by the P. & O. steamer to Australia, and since then small quantities have been exported from time to time to the same destination. From the interesting circular of J. O. Klütgen of Rotterdam, a translation of which appeared in your paper of the 5th, I find that a large demand for the article has recently sprung up in Holland, Germany and Belgium.

To supply the export trade, dealers are in the habit of collecting the article throughout the villages in the interior; principally in the Matara and Tangalla districts and in the Central Province. The season commences in May, and only one crop can be obtained during the year. The trees bear in about two years' time, but the produce is then scanty. They do not attain maturity till the fifth year, from which period a larger yield is obtained. It is not uncommon to gather 1,000 to 1,500 fruit from a tree. The flying-foxes appear to have a partiality for the tender pods, and they also feed on the flowers. When the pod is fully matured, the cotton is subject to the depredations of squirrels and birds.

The complaint hitherto has been that the staple is short and the kapok inferior to that of Java. In preparing the article for export, the chief difficulty is experienced in freeing it from the seeds. The most primitive methods have been adopted, entailing a great waste of time and labour which might be remedied by the use of suitable machinery. The improved Patent Saw Cotton Gin with new patent condenser appears to be well adapted for this purpose, as the sample of clean kapok turned out by one of these machines recently imported by Messrs. W. H. Davies & Co. was very satisfactory.

A native collector has supplied me with the following out turn :—

31 per cent kapok.
47 „ seed.
22 „ refuse.

These figures canot be guaranteed as regards the percentage of refuse and seed, but the outturn of clean kapok may be correct.

For export, the cotton is packed in bales of different sizes, containing from 112 lb. to 224 lb. The expense of embaling, as well as high freights, in addition to the great wastage in preparation, have not rendered the trade a very profitable one. The cultivation is by seed. Cuttings of the stem also grow freely. The latter are generally employed as hedges for native gardens.

NOTES ON WARRAS.

BY W. F.

For the benefit of our South Indian readers, we here give Mr. J. G. Baker's abbreviated description from Flora Brit. Ind. 2, p. 228, No. 5, of Wight and Arnott's plant, and, in addition to what is mentioned by Mr. Baker about the "pods being finely pubescent, and often covered with *red viscous glands*," we add the following from W. & A.'s description :—"Legumes pubescent, villous on the ventral suture, densely covered with *clammy red glands*," showing, in fact, that the terms "viscous" and "clammy" mean the same thing. Of course, the *Flemingia rhodocarpa*, BAKER, of the Flora of Tropical Africa (meaning the red-podded F. and the real source hitherto of the famous Waras) will take its place as a synonym of the Indian plant.

We have not the Flora of Tropical Africa to refer to, to enable us to compare the climate in which the Waras plant grows with that of the Nilgiris where Wight, Gardner and others found the Indian plant, to enable us to venture an opinion whether the Nilgiris plants will be found to produce the clammy red glands on the pods which form the Waras, in the same proportion as the African ones do; but we trust these notes will enable Professor Lawson or some other person in the Madras Presidency to test and prove whether Madras can supply Waras as well as Africa.

To those who may be inclined to cry "*cui bono*" respecting such establishments as Kew, we reply that the science and experience gained to enable Professor Thistleton Dyer and his confrères to clear up such mysteries as those connected with the origin of Waras, the medicinal rhubarb of commerce, the rice-paper plant of China, the medicinal gum Euphorbium and other valuable drugs, the source and origin of which have been a mystery for several hundred years, and which have been lately traced to their true source through the staff of the Royal Gardens at Kew, are worth all the money spent, apart from other considerations.

We now give the full account of the Indian plant which produces the Waras of Tropical Africa :—

6. F. GRAHAMIANA, *W. & A. Prodr.* 242;—F. rhodocarpa, Baker, branches subteretc, leaflets obovate obtuse or subacute thinly silky below, bracts linear firm small, calyx shaggy. F. pycnantha, *Benth. in Hohen. Pl. Exsic.* No. 1211; *Pl. Jungh.* 245.

Nilghiris, *Wight, Gardner*, &c.

A low erect shrub, with tomentose young shoots. *Stipules* lanceolate, $\frac{1}{4}$—$\frac{1}{3}$ in., caducous; petiole $\frac{1}{2}$—1 in., erecto-patent, not winged; leaflets subcoriaceous, 2-3 in. long plicate, glabrous above, grey-silky especially on the ribs beneath many of the veinlets raised. *Spikes* dense, oblong, 1-2 in. long, often fascicled; bracts under $\frac{1}{2}$ in. long, erecto-patent, subrigid, subpersistent. *Calyx* $\frac{3}{8}$ in.; teeth plumose, linear-setaceous, subequal. *Corolla* not exserted. *Pod* oblong, $\frac{3}{8}$ in. long, finely pubescent, and often covered with red viscous glands.

TEA CULTIVATION AND MANUFACTURE.

Since writing on the above subject, another issue of the *Indigo and Tea Planters' Gazette* has reached us, and we see that the subject dealt with this week is "Tea Rolling." Although this article, like the previous one on "withering," is sensibly and well written, the internal evidence seems to point to the writer not being a practical planter himself, for he commences by saying that "as soon as the leaf is sufficiently withered it is put *into* the rolling *table* and *knocked* about and gradually compressed, etc," Of course what is meant is that the withered leaf is put into the *box* of the roller, where it is tossed or worked about and at the same time gradually compressed against the subjacent table. No roller that 'knocked the leaf about' would be tolerated for a moment. It is rightly asserted that the question of hard or light rolling depends chiefly upon the state of the withered leaf, and that the object of rolling is not to express as much juice as possible, but simply to insure the thorough breaking up of all the sap-containing cells. However, as any juice that is squeezed out can easily be caught and restored to the roll, its expression is but a minor consideration. The main argument *for* hard-rolling is that it turns out stronger tea; and *against* it, that the fine pekoe tips are blackened by the process.

This latter objection, however, can be largely obviated by sifting out the tips and rolling separately. In days which are now rapidly being consigned to the period of antiquity, three, four, and even more rollings were considered absolutely essential to ensure a good twist; but now the almost universal opinion is that it is best to have one thorough rolling and be done with it.

Our Indian contemporary says :—"One great thing to be looked to is to keep the rolling mass of leaf in as cool a condition as possible, and it is, we think, a few marks in favour of whatever table does this. To keep a mass of say 160 or 180 lb. of withered leaf tossed about in a perfectly cool state is, of course, impossible, but we consider it an advantage in any table that can keep it as nearly in its normal heat as possible, and some of the tables advertized profess to do that. The sudden exposure, whilst the leaf is lying fermenting, to a cooler atmosphere than that in which it has been, causes the leaf to assume a dull leaden colour instead of a bright copper one." Now we can testify from personal experience that Jackson's Universal not only professes to, but actually does, keep the leaf as nearly as possible in its normal heat, or coolness. We have heard of some rollers into which the hand could not be put without discomfort, consequent upon the intense heat of the roll. Such a condition of things is not the right one and ought to be remedied as speedily as possible.

Before leaving the *Indigo Gazette*, we make the following extracts from it, showing that this peculiar monsoon is proving no more beneficial to Indian gardens than it is to some of our Ceylon tea estates :—

Tea is backward in Lakhimpur. The weather is hot, and cholera prevails.

The prospects of tea in Nowgong are reported not good. The weather has been too cold and deficient in rain. Every garden is behind last year.

The general remarks on the state of the season and prospects of the crops in Assam for the week ending 19th June are :—Weather warmer and rain slightly heavier than last week. Tea over the whole province is backward.

The weather has been very warm in Cachar, and there-

fore favourable for tea, but the outturn up to date has been short.

That prospects are brightening up a little, however, the following paragraph from the *Indian Daily News* seems to show :—

Tea cultivation is backward throughout Assam this season. Blight, which has been very general, has kept the plants from putting forth leaf. Good tea weather is being now experienced, however, and, under the influence of rain and sun in happy proportion, the gardens are showing signs of recovery.

The method of plucking only two-and-a-half leaves is called in Darjiling *kuppo-paro* : *paro*, we think means "leaf," but we are not sure about *kuppo*.

In another column a correspondent gives an extract from a private letter regarding tea at the Health Exhibition. We must conclude our remarks today with the following extracts upon the same subject from the "London Tea Letter" of the *Indigo Gazette* :—

I am afraid neither Indian tea nor Ceylon coffee will derive many fresh clients from the cups of both dispensed from the Indian and Ceylon cafés at the Health Exhibition. I tasted both this work and don't know which did least credit to their names. The "milk," notwithstanding a notice stuck up, to the effect that it is supplied by a particular dairy having a model dairy at the Exhibition, was sufficient to spoil anything with which it might be brought into contact, save, perhaps, a filter. The Show of Indian and Ceylon teas can only be called deplorable, and an excellent opportunity has been thrown away.

Much might have been done at this popular and really capital exhibition to make Indian teas create quite a sensation. A really good agent, with the present charmingly situated Indian Café overlooking the fountains, was all that was required, bar a little judicious advertising. 50,000 people having been visiting the exhibition daily of late, the opportunity cannot be questioned; that it should be a *coup manqué* is not a cause for satisfaction in these times; particularly as we shall probably find John Chinaman well to the front when his highly decorated court is finished. China does make exquisite tea, and doubtless John will make up for a late start by supplying a superlative quality, *versus* the toast-water and skim of the Indian dâk bungalow.

COMMON AND BOTANICAL NAMES OF PLANTS: THE CAPE JASMINE OR *GARDENIA FLORIDA*.

We hope our correspondent who asks some questions on the above subject will excuse us for giving an extract from his precise and intelligent letter in reference to this question, and accept these notes inreply.

The *Gardenia florida*, or Cape jasmine, was introduced to Ceylon, according to Moon (Additions, part 1), about sixty years ago, and has been assiduously cultivated in various parts of the island ever since, the double-flowered variety only as far as we know, and, though large plants of it have been grown here which produced few flowers, the plant is now becoming a favorite, and its large flagrant double white flowers, like a small rose or a camellia, are produced by cultivation in abundance on comparatively small plants. When a small plant grown by Mr. Robinson, the late Traffic Manager of the Ceylon Railway, produced several hundred flowers at the same time, we received notice of the fact, but we now beg to give the following information to our correspondent, which we hope will be acceptable to others of our readers interested in such subjects.

The specific or trivial name "florida," given by Linnæus to this plant in 1764, does not mean that it is a native of Florida, but that the specimens before him, when he named it, indicated that it was a very *florid* or *flowery* plant ; hence the *Gardenia florida*, which properly is a native of Japan and China, and travelled to the Cape of Good Hope, where it grew as it does in Ceylon, and was named (erroneously) by Miller in his Dictionary &c. (in 1768-1831?) *Jasminum capense*, and from this blunder on the part of Miller, the truly native of Japan and China is called the "Cape jasmine," and the name cannot now be altered. It is of course one of the *Rubiaceæ*, and the jasmine, of which our correspondent sends us one leaf and one flower, is, as he correctly diagnoses one of the olive family.

The double-flowered plant, of the very commonly cultivated one of *Tabernæmontana coronaria*, Br., described by Sir Joseph Hooker in Flora British India, vol. 3. p. 646-7, and collected here by Paul Herman in 1670-76, is so like the *Gardenia* in general appearance, that Willdenow, t. p. 1225 has a long note on the *Jasminum zeylanicum* of Burm. Flora Zeyl. t. 59 for this latter plant, in connection with the *Gardenia florida*, which are certainly like each other in respect to their double white flowers ; but the one is a Rubiaceous plant, and the other is a Dogbane with milky juice, the "native country of which is unknown."

W. F.

"I am taking the liberty of writing to you now (upon a botanical question that has been puzzling me), as your name is connected with the pamphlet from which I quote. I refer to the 'Hints on Gardening' by W. Cameron with notes by yourself.

"On page 7—6th line from top—is mentioned 'Gardenia Florida' after which 'Cape Jasmine' is inserted in brackets. Now the plant which we all (upcountry) call Cape Jasmine must be, I think, a different one altogether. I enclose a blossom and leaf. It is a shrubby creeper with simple leaves, and the flower contains only *two stamens* and the ovary is *superior*. For this reason, I have referred it to the nat. order Oleaceæ of which 'Jasminum' is a tribe.

"The Gardenia family, I find in 'Oliver's Indian Botany' is a subtype of the Rubiaceæ and has *five stamens* and ovary *inferior*.

"I therefore think the plant of which I enclose a blossom must be the 'Jasminum Sambac' of 'Oliver,' and that the 'Gardenia Florida' in 'Hints on Gardening' is the common gardenia in upcountry gardens, the name Cape Jasmine being wrongly applied to J. Sambac.

"I hope you will excuse my troubling you on the subject, but I should be very glad to know which is the true Cape Jasmine."

"INDUSTRIAL AND COTTON CENTENNIAL EXPOSITION" AT NEW ORLEANS.

The United States Consul in Colombo writes :—

"I enclose herewith copy of a dispatch from the Secretary of State, Washington, anent the Great Exhibition to open at New Orleans on the 1st Monday of December this year ; and as the event offers an excellent opportunity for the introduction of Ceylon products to a rich section of the United States, where they are at present unknown, perhaps you may be inclined to give publicity to Mr. Frelinghuysen's letter in your newspaper."

The report of the Director-General states that already, in recognition of the formal invitation through this Government, eleven foreign Governments have indicated an intention to participate, and many others have only delayed action while awaiting information as to the progress of the preparations.

The applications for space, however, by foreign and United States exhibitors eight months before the opening, require about 900,000 feet, and, although the exhibition building is the largest ever erected except that of London, it has already been found inadequate for the area demanded.

The ample resources of the Association, however, it is thought, insures the ultimate accommodation of all participants.

Congress required that the city named as the location for the exposition should subscribe to the amount of $500,000.

In addition to a compliance with this requirement, the Corporation of New Orleans has contributed $100,000 and

the use of its principal park containing 247 acres of ground; the Government of Louisiana will recommend a liberal appropriation by the legislature, and the board of management have called upon the citizens to increase their subscription to $1,000,000.

At the near assembling of the legislatures in the several states and territories of the United States, particular attention will be directed to supply local representations upon a commensurate scale, and already the people of different districts and counties of the country have perfected organizations for the purpose of securing by private contribution a local display by their respective states.

The desirability of having exhibited suitable articles and designs from the various executive departments of the General Government has been recognized by the President, who has ordered that a board composed of one person designated upon a nomination by the head of each department of the Government, and also of one named in behalf of the Smithsonian Institute, one in behalf of the department of Agriculture and one in behalf of the bureau of education, shall be charged with the preparation of the materials for an exhibit illustrating the functions and administrative faculties of the Government.

The main building is 1,375 feet in length and 905 feet in width, affording 1,300,000 square feet of floor space, with convenient apartments attached for police, fire department, public comfort, offices, meeting-rooms for various national organizations, and with a central music-hall capable of seating 11,000 persons and a machinery-hall 1,375 feet in length by 250 feet in width. Extensive accommodations have here been provided for the display of factories of all varieties in motion.

The horticultural hall is said to be the largest conservatory ever erected. It is 600 feet in length, 194 broad in the centre, with glass roof, a glass tower 90 feet in height, with heating apparatus and cold storage attachment for preserving fruit. It is designed to have an international exhibition of plants and shrubbery around the sides of this building under cover, and an international display of fruits extending throughout the central spaces of the building.

Mexico has consented to adorn the main centre with royal palms and native plants, and will occupy 200,000 feet of space adjoining the hall for a garden.

The Republics of Central America will adorn 250,000 feet of the garden, and an equal extent will be occupied by floral products of Florida and California.

At art gallery of native marble is to be provided, and every effort will be made to accommodate the extensive collections of art treasures and antique relics now at the command of the Association. One thousand feet of space in the main building has been designed for an agricultural hall.

Forty acres of ground have been laid off for growing farms, experimental and vegetable gardens, and forty acres provided for buildings to accommodate live stock, poultry and birds, with a half-mile stock arena wherein sales of animals will be permitted on stated days.

Suitable arrangements have been made for a national educational display upon the endorsement of the National Educational Convention and the cordial co-operation of the United States Commission of Education, and appropriate steps have been taken for the organization of a department of woman's work under the high direction of those interested in offering women an independent position in the economy and industries of the world. The Exposition grounds will be embellished with six lakes, and generous collections of evergreens from the United States and the Latin American countries, presenting groves of the cedar, pine, pomegranate, magnolia, lemon, palm, orange, coconut and banana.

The conveniences of transportation for visitors and contributions have not been overlooked.

One hundred and fifty lines of railroads have agreed to a maximum rate on passengers of one cent per mile, and excursion rates will be frequently introduced.

Both passengers and freight can be brought by a railroad into the main building, and a wharf adjoining the Exposition grounds will be provided for the accommodation of visitors and exhibits arriving by steamships or steamboats.

ARTESIAN WELL-SINKING.

In connection with the recent discovery of an artesian spring in the Far North at a depth of 1,220 feet, the following account of a still deeper boring successfully achieved in the city of Pesth, in Hungary, will doubtless prove of interest. It is extracted from a Hamburg paper, the *Reform*, and is as follows:—"The well has been already sunk 951 metres (3,366 feet) in depth, while the artesian well of Paris is only 547 metres. Since June the boring has been through dolomite for a distance of 33 fathoms. The water obtained is pure as crystal, contains chalk and sulphur, and is so warm that it stands at 57·6 Réaumur (about 162° Fahr.) on reaching the surface of the earth. The stream which is thrown out in 24 hours amounts to 6,939 hectolitres (152,680 gallons), and this quantity can be increased by a daily supplement of over 1,000 hectrolitres. It is the intention of Herr Zsigmondy (the director of the work) to go down until he reaches a heat of 65° Réaumur, and obtains a supply of warm curative waters sufficient for the various city baths. The scientific results of the sinking, which has extended over several years, are very great, and not less important are the technical inventions which the necessities of the undertaking almost forced Herr Zsigmondy and his brother to make. We may mention, by way of example, that they managed the feat of driving in a nail at this enormous depth, when required, and also to withdraw it by means of the magnet, if it happened to be wrongly placed; they cut off iron wedges driven in with a force of 10 cwt., also broken pipes, and drew them up out of the bore, while an ingenious invention of Herr Bela Zsigmondy, by which the boring is effected by means of the up stream of water, does this work twice as quickly as by the old system of pressure from above. It is also of interest to note that the degrees of heat registered at different depths are altogether at variance with the results of previous observations. The water shoots into the air to a height of thirty-six feet, and is at present led off into the canal When once the well is finished it will be possible to utilize the warmth obtained so as to turn that part of the Stadtwaldchen into a perennial summer garden, while the water can be carried through the city in pipes for curative purposes." There is another interesting Artesian well at Saint Etienne, which M. F. Laur describes as follows:—"This well brings the water from a depth of 502 metres, and causes it to spurt at intervals to a height of 26 metres above the ground. The diameter of the tube which conducts this spring of thermal and very gaseous water is 21 centimetres. The appearance of this column is, owing to phenomena, identical with those of the famous geysers of Iceland. It is susceptible of being artificially provoked in several ways, and throws consequently considerable light upon the mode of formation of these astonishing volcanoes of boiling waters. M. Yamin has named a commission of five members, who are to repair immediately to the scene to study these phenomena. In fact, these will cease to be visible as soon as the works are commenced to get the waters under control. The President appointed of this Commission is M. Daubrée, whose competence is known to all, and who, we are persuaded, will return with a report worthy to be placed by the side of those which have made the reputation of the Academy, and which have become too rare since the death of Arago. In the meanwhile, it is fitting to congratulate the engineer who has observed this singular phenomenon, and who has conceived the excellent idea of bringing it to the attention of the Academy before it was too late to set out to make an examination upon the spot."—*Adelaide Observer.*

A COMPANY of Chinese has applied for 200 acres near Port Darwin for rice-growing.—*Queenslander.*

THE HEALTH EXHIBITION: TEA.

This is so numerously represented by the growers themselves, in the case of Indian teas, and by their agents, and also by importers and dealers in the article, that a few notes of the more original and more varied collections of the planters and their agents are all that we shall be enabled to notice at any length. In the Indian court on the west side of the buildings the District Association of the Kangra Valley has a very complete assortment of the herb, grown in the country in which the undertaking in question is established. It appears that there are between 300 and 400 different varieties, or perhaps more correctly speaking flavours, as flavour will vary more from soil, shelter and altitude, and are more appreciable than any differences caused by variety, time of picking or subsequent manipulation. Here are found about twelve distinct varieties of manufactured tea from Kangra, placed in glass-covered boxes where it is possible to note such differences as form, size and colour, the intelligent Hindu in charge being most obliging to answer any questions the visitor may put to him respecting them. There are also on view a portion of the trunk of a tea shrub of about 4 inches in diameter, equalling therefore that of an old Gooseberry bush, say of twenty years; tea seeds, photographs representing views in the district of Kangra, operations in the cultivation and manufacture, very English-looking square-towered churches, and dwellings in Sylhet, Cachar and Assam. Taking out the mountains in the distant views, and substituting short-petticoated Irish garden-women for the semi-nude Kangraites, we might take some of the photographs to represent the regularly planted small fruit farms of Kent, so much, too, do the bushes resemble them. On this same stand are to be found a few samples of Mysore, Tellicherry and Neilgherry coffees; and a case containing samples of indigo from places far distant from each other, as Java, Oudh, Madras, Bombay and Benares, and several with quite local appellations. Specimens of tea growing in pots are also on view; these consist of the wild species of T. sinensis and T. viridis, T. assamica, as well as some hybrid forms possessing mostly creamy variegation on the leaf. Another Indian bazaar near this was tenanted by Hindu attendants, and an Englishman, Mr. Bowden. The construction and fittings are as completely Indian in appearance as materials, and a knowledge acquired by long residence in the country can make them, the native women in their costume adding much to the idea desired to be conveyed. In this bazaar are samples of teas of a more varied description than is seen at the Kangra stall, while the proprietor is an agent for those teas generally that are produced on Indian soil. These are packed in air-tight metal-like paper, but which is a true metal that can be soldered by merely passing a hot iron over the edges. As this is a bazaar proper it is only to be expected that we should find a varied and curious assortment of native wares, such as curries and what they are made of, pickles of the warmest, a preserve made from Physalis Alkekengi, the Cape Gooseberry, said to be superior to that of Guava, in that its flavour and aroma are less evanescent and more delicious; Trichinopoly cigars made from a tobacco called Lanka; peppers to stimulate the flagging appetite; and Indian toys for babies brown and white, whose colours are as fast as their own, for they cannot be licked off—an advantage not to be overlooked by owners of infants. Coloured models of Indian fruits of many species form an interesting portion of the items seen at this stall, and we must not forget the toddy gatherer and his wife. As this intoxicating liquid is made from the juice of the fruit-stalk of Borassus flabelliformis, a species of palm that attains a height of 70–100 feet, it is necessary, to get the "basis," to climb the tree to the top, where the long bunches of fruit hang. These fruits are of the size of medium Oranges, and it is from their foot-stalk that the liquid slowly drips. A fruit is cut off and a jug hung on to catch the juice, so that there may be several hanging on one bunch. These have to be placed in position in the early morning and removed in the evening, so that our toddy-tapper has quite enough on his hands when he has ten or a dozen Borassuses on draught. His wife, of course, carries the jars and he does the climbing business, which is done by means of a strap round his waist and by fastening his feet near the ankles with another, so that by leaning back against the waist-strap, his feet being placed against the stem, he can ascend by a series of jerks.—*Gardeners' Chronicle.*

CEYLON AND INDIAN PRODUCE.

The following extracts from the *Produce Markets' Review* will, we are sure, prove interesting to our readers:—

The first arrivals of the new season's Black Leaf Congous are due about Thursday next, and within three weeks from that time the immense quantity of 18,000,000 lb. is expected to reach this market. The stocks here are already superabundant, and the production is increasing rapidly in India, Ceylon, and Java, of teas, which, as a rule, are far stronger and better than the China growths. Really fine Black Leaf Congou of the first pickings of the last crop is now to be had in the London market 9d or 10d a lb.—prices which are probably 6d below those refused for the parcels when they first arrived. Under such circumstances the average value of China tea in the season about to open, can only be very low, particularly if the supplies are hurried forward, as is now being done. Instead of tea here being cheaper than was ever before known, and of stocks being greatly beyond the wants of the trade, it might be thought that the China Merchants were hurrying to fill up a great gap in the supplies at highly remunerative prices. As, however, we are suffering from a glut, and not from a scarcity, of tea, the course for the trade to pursue is unusually well remarked out. It is clearly to let the great supplies of new tea accumulate, until the prices reach a low level.

So long as grocers can buy all but the very finest Congous at certainly under 1s per lb., and can add any constituents these may want from the abundant supplies of fine Indian teas, in what way do the new season's Black Leafs interest them? On the other hand, if they give more for them than for similar qualities of old tea, they will simply involve the whole importing and distributing trades in another season of loss and constantly-increasing depression. The trifling greater freshness of new teas is of no real advantage, for it is soon lost, and it can, besides, be little appreciated even at the first by the public, after the addition of milk and sugar.

Indian teas are selling fairly, and the market is steady for most grades. The few breaks of new Darjeelings offered were scarcely up to the average, except one or two lots, but as is usually the case with the first arrivals, they attracted attention, and fetched much higher prices than similar grades of old import. The latest estimate of the Indian crop is slightly in excess of that previously reported, but it is also said that the season is likely to be a backward one; as there is an ample supply of old teas here, this is not of much consequence. The quality of the new crop is reported to be good, and it is of equal importance that prices in Calcutta have opened considerably lower than last year. From this it would appear that buyers in Calcutta are alive to the probable course of the market. At any rate, with larger shipments from Ceylon and Java, there is every probability that a lower average of prices is to be expected than during the past season, and if this is well considered by those who buy tea in Calcutta at the sales, their frequent heavy losses would probably come to an end. At the public sales 7,300 packages of Indian, including 313 new season's, 926 of Ceylon, and 702 of Java teas, were offered. For the former there was a steady inquiry, but the Ceylon growths were eagerly competed for at firm prices. The Java teas sold readily, at quite former rates.

From the *Home and Colonial Mail* we take over some important statistics of the great Indian Tea Companies. The area of the Lebong Tea Company, Limited (in Darjiling), is 988 acres and the expected out-turn this season is 276,000 lb. of extra fine tea (say 270 lb. per acre). Last season's crop was 277,899 lb. produced at an inclusive cost of 1s ½d a lb., and realized an average of 1s 5½d. The profit from tea was £5,545, from sale of tea-seed £857, and interest on £35,000 invested capital £1,750, making a total sum of £8,152, admitting of a dividend of 9 per cent. The revenue account for the year showed the estimated receipts at £22,487-11-8, less total expenditure £14,335-9-1 ; balance estimated net profit £8,152-2-7, as above.

The Borelli Tea Company, Limited, has an area of 875 acres under cultivation. The annual report runs as follows :—

From the causes explained in the circular dated Jan. 1st last, the crop amounted to only 388,820 lb. of packed tea, showing a falling off, as compared with the preceding year, of 38,110 lb. Owing, however, to increased economy in the working of the estates, and a rather higher average in the price obtained for the crop, the profit on the year has been £3,022 5s 2d. This, with the balance at credit of revenue, £4,038 15s 9d., after deducting the closing dividend on season 1882, and adding the profit under-estimated on that year, admits of the payment of a final dividend of 4 per cent., making 8 per cent. for the year, and leaving a balance of £3,807 8s 11d. to be carried forward. The gross average price realized for the crop is 1s 1·955d., and the laid down cost 10·237d. per lb. The latest reports from the superintendent show the estates to be in good order throughout. The extensions made last year have proved very successful, and a further addition has been made this season of 55 acres, which promise to do equally well, bringing the total area under cultivation up to 875·52 acres. All these extensions have been charged to revenue. The Superintendent estimates the crop of the current year at 436,000 lb. of tea, at an expenditure of about 10d. per lb. laid down. The Company's recruiters having been exceptionally fortunate in bringing up a large number of coolies, additional facility will be afforded for taking off the leaf at an earlier stage of development, with a consequent improvement in quality. With the view of promoting this object, it has been arranged that Mr. Denton, a tea taster of considerable experience and proved capacity in the employ of the Calcutta agents, shall pay a visit to the estates during the manufacturing season, and give Mr. Lumsden the benefit of his advice and assistance. The Report and Accounts having been received and adopted, a final dividend of 4 per cent. making 8 per cent. for the year was declared.

Since the Company was started in 1874 the following are the average prices obtained for the Company's crops of tea, and the dividends declared year by year. It will be noted that the average dividend is nearly 10 per cent.

	Average value tea per lb.	Dividend declared.
1874	1 9¼ ...	10
1875	1 9⅛ ...	12
1876	1 9½ ...	13
1877	1 10½ ...	14
1878	1 9¾ ...	10
1879	1 5½ ...	10
1880	1 2¾ ...	4
1881	1 4¾ ...	10
1882	1 1 ...	8
1883	1 2 ...	8

STATEMENT OF ACCREAGE UNDER CULTIVATION, ACCORDING TO SURVEY.

TEA CULTIVATION.

Name of Plantation.	Old.	1881—2.	1882—3.	Extensions made this season about	Total acres.
Paiupoota ...	...395·73 ...	10· ...	— ...	6· ...	411·73
Bokagaon ...	...202·22 ...	6· ...	4· ...	19· ...	231·23
Hauchoora ...	... 79·31 ...	10· ...	50· ...	30· ...	169·31
Patgaon ...	... 63·26 ...	- ...	— ...	— ...	63·26
Total.....	.....740·52 ...	26· ...	54· ...	55· ...	875·52

We note that the expected crop of the above concern was at the rate of 500 lb. per acre, and that in 1877 the average price was 1s 10½d and the dividend declared was 14 per cent.

The report of the Jhanzie Tea Association, Limited, was not quite so satisfactory : the causes of failure were said to be two-fold :—First, owing to unfavourable weather in the Jorhāt district, in which some of the gardens are located, the out-turn fell short of estimate by 48,000 lb. ; second, the quality of the crop, possibly affected by the weather, was, though better than 1882, inferior to 1881.

The sale of 211 maunds Tea seed realised R17,704-9-6, or at the rate of about R84 per maund. The coming crop of seed is estimated at between 300 and 400 maunds, but the demand at present is very small. In machinery the manager reports well of the Gibbs & Barry's drier, and the two siroccos. On the garden was a labour force of 490 men, 401 women, and 89 children. Unfortunately there had been three outbreaks of cholera, which had resulted in the death of about 60 Bengali coolies, and the absconding of 50 Kacharies. The manager's estimate for 1884 is for a crop of 344,000 lb., including Nagani Jan (an estate they were in treaty for,) for an Indian outlay of R140,000, equivalent to 8¼d per lb. f. o. b. in Calcutta, at an exchange of 1s 8¼d per rupee.

WELL-MANAGED clay soil is known to be capable of yielding the largest crop of grain. The reason usually given for this is that clay is retentive of both manure and moisture. But there is another reason of scarcely less importance. Insects that attack the roots of plants, living unseen, and often unthought of or unsuspected, find it difficult to live or work in clay. They cannot penetrate it, or they perish in it. And these insidious enemies are the worst that the farmer or gardener has to contend with.—*Queenslander*.

INSECTICIDE.—The following is the best method we are acquainted with for making the kerosene emulsion:—Dissolve ½lb of soft soap and a lump the size of a walnut of washing soda in a gallon of boiling water; into this pour 4 oz. of kerosene, stir it well, and add 4 more gallons of water, stirring well again, and you will have a mixture that will destroy nearly all kinds of insects, and not injure many plants; but of course you must be cautious with plants of tender nature, trying it first on a single plant or part of a plant. It should be washed off after a few hours. It will keep for any length of time in close jars or bottles.—*Leader*.

JAPANESE LACQUER.—In a recent communication to the Asiatic Society of Japan (*Nature*, April 24), Mr. O. Korschelt gave some very interesting information respecting the constituents of Japanese lacquer. He considers the raw lacquer juice to be an emulsion which contains a peculiar acid (urushic acid), a gum, a nitrogenous body, water and traces of a volatile acid. The hardening of the juice that takes place when it is exposed in a thin layer to moist air at a temperature between 20° C. and 27° C. is due to the oxidation of urushic acid to oxyurushic acid under the influence of the nitrogenous body, which acts as a ferment. Whilst the gum is useful in maintaining the condition of an emulsion, its presence in the hardened lacquer is injurious, as it gives rise to blisters in contact with water. The reduction of the proportion of gum by the admixture of raw juice with separated urushic acid, is therefore, advantageous; but on the other hand, if this admixture be carried beyond five parts of acid with one part of juice the activity of the ferment is interfered with. The ferment is an albumenoid, but contains much less nitrogen than albumen, and it cannot be replaced by diastase or ptyalin. The quality of the lacquer seems to be dependent upon its richness in urushic acid and poverty in water, the durability of the finished work being due to the oxyurushic acid, which is singularly negative in its reactions, resisting all solvents tried, and being affected only by strong nitric acid. What is known as lacquer poisoning is stated to be due to urushic acid, which gradually disappears; the best antidote for it is sugar of lead.—*Pharmaceutical Journal*.

Correspondence.

To the Editor of the Ceylon Observer.

PERFORATED TEA LEAVES.

Maskeliya, 21st June 1884.

DEAR SIR,—Enclosed are a few "tea leaves." You will see they have the appearance of being pricked with a pin. I picked them off two of my bushes today, one of the bushes hardly had a sound leaf on it. The bushes are five years old and have been bearing seed, but I cut them down about two months ago. Can you tell me what has caused marks on the leaves?—I am, yeure faithfully, HUGH BLACKLAW.

[Our entomological authority states :—"The holes in the tea leaves may have been caused by small beetles (perhaps weevils) feeding on them. They should be looked for. Similar damage might possibly be produced by small caterpillars."—ED.]

QUESTIONS ABOUT THE CROTON OIL PLANT.

June 22nd, 1884.

DEAR SIR,—I would be much obliged if you or any of your numerous readers could let me know what distance apart the croton oil plants should be planted, and also if it will grow and fruit under the shade of Ceará rubber trees.—Yours faithfully,

NEW PRODUCT.

[Mr. Holloway may, perhaps, give replies.—ED..]

PARAMERIA GLANDULIFERA.

Peradeniya, 26th June 1884.

SIR,—M. Pierre's letter to "a Ceylon planter" being printed in your columns, I may perhaps be permitted to communicate with the latter anonymous gentleman through the same channel.

The gardens here do not possess *Parameria glandulifera*, several endeavours to obtain the plant having been unsuccessful. The statement in M. Pierre's letter, that this rubber-yielding climber is abundant in the South of India, is erroneous. In his original communication on the subject, as abstracted in English in the *Colonies and India* (12th May 1882) and thence transferred to the *Tropical Agriculturist* (July 1882, p. 78), this statement is not made ; the error arose subsequently by a curious oversight in the Kew Report for 1881 (p. 47), whence it has been probably derived by M. Pierre. *Parameria* grows nowhere either in Peninsular India or Ceylon ; to the other localities given—which are correct—may be added the Andaman Islands, along the borders of tidal forests. The plant is described in the new "Flora of British India (III, p. 660) and was long ago figured in Wight's "Icones" (t. 1,307) as *Ecdysanthera glandulifera* from Malacca.

The attention of the Indian Government was called to this rubber plant last year by the Deputy Commissioner of Mergui, British Burma, the "Talaing Milk Creeper" of that district, according to Dr. King's identification of very inadequate specimens, being the same species. The reports as to its yield there are somewhat conflicting : the Deputy Commissioner states that he obtained about ½ lb. of rubber from a piece of stem 80 ft. long and 8½ inches circumference by extracting all its juice, but, according to the Director of Agriculture of British Burma, this is not a fair estimate, as "a bottle full of the milk" was obtained from "a few feet of the creeper." Dr. Romanis, chemical examiner, states that "one pint of juice yielded 13½ oz. of caoutchouc," which appears a very high proportion. The specimen of rubber received by Dr. King he describes as "externally considerably discoloured and almost black from being partially oxidized. When cut into, it is white and porous, presenting a honeycombed appearance, the spaces containing a dirty-brown watery fluid. It is tough and elastic, and appears to be of excellent quality."

This information, with that contained in M. Pierre's publications and letter, is, I think, all at present available on the subject.—I am, sir, yours faithfully,

HENRY TRIMEN.

TEA JURY AT THE I. H. E.

4, Guildhall Chambers, 33, Basinghall Street,
London, E. C., 27th June 1884.

DEAR SIR,—We shall feel obliged if you will give publicity to the following correspondence. Our object is to show our friends in Ceylon how the matter of awards for tea stands at present, and also to defend ourselves against any subsequent charges of carelessness etc. that might otherwise be brought against us. We have to explain, as preface to the correspondence given below, that we were requested by the Chairman of the Health Exhibition to nominate three gentlemen to represent your island. We lost no time in setting about so pleasant a task and obtained promises from Messrs. King and Forbes Laurie and Captain Hayes to act ; it was only when forwarding the names of these gentlemen we were told the jury list was filled up, and we were also informed that the tea then before them would only be judged upon! In reply to this last most novel and vexatious regulation we strongly represented to the commissioners that we had their Secretary's assurance that samples would be in time by the middle of July. For the comfort of those most interested we may add that we believe we can bring other pressure to bear, and that we are still of opinion that the awards will be kept back until the middle of July, thus giving time for us to receive samples sent in reply to our last advertisement calling for them, and we are hopeful of obtainiug for Ceylon tea at least one of the very small number of gold medals given. Your teas are in open competition with India and China, but each estate's sample will be put in on its own merits. We shall have more to write you in another fortnight. In the meantime the jury are tasting Indian teas, which we understand are last season's, the fact being that the new season's tea have not yet come to hand ; and the greatest indignation is expressed by those concerned in the Indian teas, and like ourselves they are asking for time.—Yours truly, HUTCHISON & Co.

June 19th, 1884.

To the Chairman, Jurors' Office, I. H. E., South Kensington.

SIR,—We have the honour to bring to your notice the following fact :—

About a fortnight ago you favoured us with a notice asking us to nominate gentlemen suited as judges of tea, on behalf of Ceylon. On receipt of your communication we at once put ourselves in correspondence with different gentlemen with whom we were acquainted, three of whom have kindly volunteered to act as jurors. On application to your office today, our Mr. Ames was informed that the tea jury (No. 3) was already filled up. We respectfully request that you will so arrange as to include at least one name of those we have to submit to you. Otherwise Ceylon will be entirely unrepresented on your Board.

Regarding the time for exhibits to be remitted to the jury, we have already explained to your Secretary that owing to seasons it has been quite impossible for us to have samples in before July. The picking in Ceylon, and, we believe in India, generally begins late in April, and it is impossible for new samples to arrive sooner than ours can. We have spared no trouble or expense in writing, advertising, and urging planters in Ceylon to forward us samples to submit to the jury, and we earnestly hope that justice may be extended to them and these teas receive due consideration upon arrival. So sure are we of the excellence of Ceylon teas that we are willing to put them

in open competition with either India, China, or both. Our request is that a Ceylon man may sit upon your Board and that reasonable time be allowed us to get home new season's teas.

Trusting the favour of a reply, we have the honour to be, yours obediently,

(Signed) HUTCHISON & Co.

Jury Department,
South Kensington S.W., 22nd June 1884.

To Messrs. Hutchison & Co., 4, Guildhall Chambers.

Gentlemen,—In reply to yours of the 19th inst., I regret, on account of the hundreds of similar applications, that it is impossible for me to comply with your request. You or your agent can make an appointment with the chairman of your jury personally.—Yours faithfully,

(Signed) *pro* T. WINTER, G. W. F.

South Kensington, 23rd June 1884.

The Chairman, Jury Commission, I. H. E.

Dear Sir,—In reply to your letter of Saturday (22nd) we have to say that we have endeavoured many times to see the chairman of our jury, but have failed so far to do so. We will wait upon him tomorrow at 4 o'clock, and shall be glad if he will receive us. On behalf of Ceylon and its tea-planting interests we cannot but feel indignant at this way of treating the island. It was your own courteous suggestion that a Ceylon man should serve upon the Commission, and every one who knows anything of tea-growing will agree that new season's samples cannot arrive till after June.—Yours faithfully,

(Signed) HUTCHISON & Co.

South Kensington, 24th June 1884.

To Messrs. Hutchison & Co., 4, Guildhall Chambers, E.C.

Dear Sirs,—Your letter of the 23rd has been considered by the Jury Commission. They request me to say in answer thereto that they consider tea is fully represented on No. 3 jury, and that it would be hardly desirable to add to the jury anyone who might be considered to represent a special tea-growing district. They think you may rely upon the jury giving full attention to the Sinhalese exhibits. Should you not consider that they receive sufficient attention, I shall be glad if you will inform me a little later on when the labours of the jury are drawing near their conclusion.—Yours faithfully,

(Signed) H. T. WOOD, Secretary to the Jury Commission.

LEAF-DISEASE, NEW PRODUCTS, ETC.—No. 4.

DEAR SIR,—I have been carefully reading the discussions in the last planters' meeting with regard to cacao disease. You will remember, that, in my article headed "Leat Disease, etc., No. 1," I anticipated, that, not only coffee, but all the new plantations of tea and cacao will be affected, and my anticpations, I find, are fulfilled sooner than I expected. I am no planter but I take some interest in cultivating kitchen garden and flower plants, and I have found, that, under certain circumstances the leaves and stems were sometimes suddenly destroyed. I took some pains in trying to observe the cause of the destruction. Amongst flower plants, the holly-hock presented one morning the edges of the leaves rolled up and some parts eaten—on unrolling that part of the leaf, I found small beetles of a reddish brown colour about one-sixteenth of an inch in length—which I destroyed; in another place I found the leaves simply bitten, or, as one of the planters said, looked as if they were burnt. This was evidently done by some minute worms. I however removed those leaves, and the plant is still thriving and flowering. Sometimes I found clusters of what appeared to be small lumps of cotton; within this lump was contained an insect which under the microscope revealed to be infant tarantulas.* The whole of the clusters which were connected and hanging with white fibre-like threads were removed and the plants got on well, and I took care to examine them every morning and remove every fresh collection. The holly-hock is comparatively in the shade, being nearly under the eaves of the house and on the edge of the verandah; the other plants were more exposed to the sun, they were all certainly greatly exposed to the strong south-westerly blowing and scorching glare of the sun. That the strong blowing affects and withers trees, however much they may be watered, there is no doubt,—of course, those garden plants that are not watered, suffer most and sooner—but the most important question still is: What brings on the parasitical animals in the shape of worms and insects? The occurrence of small beetles I attribute to manure being fresh. It must have been observed, that, in some localities where there are heaps of dung either of the cow or horse, there is a swarm of minute insects which will on examination be found to be the beetles I have previously referred to as rolling themselves in the leaves and destroying them. It may not be impossible that the other insects like tarantulas may be migrations from dunghill and rubbish etc., which are carried up by the wind; their progress being arrested, they settle on trees and plants where they spin the cocoons, which, I think, the white cottony clusters are, and, if they are not removed, they will no doubt breed extensively, and the destruction of trees and plants will consequently be greater.

It is an old practice, and much carried on by village people and others, when the leaves of plants and trees indicate disease by the leaves looking burnt and eaten, to throw over them cold ashes; it is surprising to observe how soon the appearance of the plants change for the better. The ravages by the worms generally take place during the dewy season; this moisture and other circumstances, I believe, generate the worms: it is possible that the cold ashes, in stifling the breathing powers of the worms, destroy them as sulphur does to itch worms, or the alkaline effect of the ash neutralizes the moisture of the plants which is become acid by absorbing some of their acid juices, and any vivifying effect which the moisture may have on the worms is destroyed.—Yours truly, SILEX.

[Our correspondent was very safe in predicting that all extensive cultures would be troubled by pests. Of course measures which are effective in garden cultivation cannot be profitably applied to wide areas, but the dusting of affected plants with wood-ashes cannot but be beneficial.—ED.]

* Tarantulas?—ED.

THE NOYAU OR NOYEAU VINE OR PLANT: *IPOMŒA SINUATA*, ORTEGA.

Kelvin Grove, Colombo, 30th June 1884.

SIR,—For several years past, when driving through Colombo with any stranger, I scarcely lose an opportunity of attracting attention to a very common and abundant exotic climber which grows everywhere here, and often covering fences and small houses with a mass of dissected green leaves and large white flowers with cerise centres, and one of the best quick-growing plants to cover an arbour or to conceal small outhouses. I attract particular attention to this plant by pulling some of its leaves, crushing them between the fingers and then presenting them to my friends, and asking them what the odour reminds them of, when the reply is variously given as "Noyau," "Cherry Pie," "Heliotrope," "Prussic acid" or "Bitter Almonds." My reply is: "This is the Noyau plant, and this is a practical lesson in botany."

Although the plant is alluded to in several works on botany as producing Noyau, I had not noted the fact until Mrs. O'Brien, the wife of General O'Brien, attracted my attention to it at Braybrooke Hall, saying: "This is what we call the Noyau plant in

the West Indies," at the same time giving me the lesson of crushing the leaves, which I have not forgotten, and which I now have the pleasure of recording for the benefit of the readers of the *Ceylon Observer* and of the *Tropical Agriculturist*.

What the liqueur sold as Noyau is really composed of is as doubtful as the composition of most other liqueurs, judging by the various accounts some of which I here give; but that Noyau, pure and simple, is manufactured from the *Ipomœa sinuata*, ORTEGA, is distinctly recorded, and from no other source, as far as my information goes. Noyau appears to be a liqueur *flavored* by several vegetable products, and this is about all the information which I can find in all the books I can refer to in Colombo.

The *Ipomœa sinuata*, from which Noyau is said to be made, was originally a native of Georgia and Florida, but was introduced many years ago to Asia from tropical America, and is now found in N. W. India, Hindostan, Bengal and Ceylon, and is cosmopolitan in the tropics. It is properly the *Ipomœa sinuata* of Ortega, and has been described as *Convolvulus dissectus*, Linn. *Ipomœa dissecta*, CHOISY, and has been figured by Jacquin Hort. Vindob. ii. 74. t. 159. and is described by C. B. Clarke in the Flora of British India (vol. 4. p. 214), in Baker's Flora of Mauritius (p. 207) and Don's Gard. Dict. 4 (p. 297).

As stated above, it is a most common plant in Colombo and to persons going into the Fort through Slave Island. I may call their attention to a plant of it which some weeks ago covered the entire roof of the last house on the right-hand-side (before crossing the railway) of the married quarters of the non-commissioned officers of the Royal Artillery; but since the south-west monsoon has set in, this plant is somewhat curtailed in its dimensions. It was introduced to Ceylon before 1824, according to Moon's Cat. Ceylon plants (p. 13).

The following are the extracts referred to above:—"*Convolvulus dissectus* abounds in prussic acid, and is one of the plants from which the liqueur Noyau is prepared.—Bot. Mag. 3141, Lindley's Vegetable Kingdom p. 631. The kernel of *Cerasus occidentalis* is used for flavouring the liqueur Noyau.—Lindley l. c. p. 558. *Ipomœa sinuata*, ORTEGA, the Noyau vine.—Schomburgh's Barbadoes, p. 612 No. 655. The statement in Eng. Cyc. Nat. Hist. 2, p. 130, that Noyau is got from *Ipomœa pandurata*, is a mistake. *Convolvulus dissectus* abounds in Hydrocyanic acid, and is said to be one of the plants from which the liqueur Noyau is prepared.—Maunder's Treasury of Botany 1, p. 326.

Noyau (Fr.), a liqueur flavoured with the kernels of *Cerasus occidentalis*; it is also said to be sometimes prepared from *Convolvulus dissectus*.—Maunder l. c. 2. p. 794. The kernels of species of *Cerasus* impart flavour to Noyau, ratafia, cherry brandy and maraschino.—Balfour's Class-book of Botany, p. 806.

Noyau, a rich cordial, flavoured with the kernels of the nuts of bitter almonds, or of peach stones.—Imperial Lexicon 2, p. 140.

Noyau, a name in France of a liqueur said to be prepared from the kernels of *Cerasus occidentalis*, a tree of the plum family (*Drupaceæ*), native of Jamaica, where it is called laurel. It is more than probable that the kernels of the common cherry are also used in the preparation of Noyau, and it is said that a species of convolvulus (*C. dissectus*) furnishes material from which the liqueur is made. Noyau is chiefly used for flavouring confectionery.—Smith's Dictionary of Names of Common Plants, p. 289.

To Dr. Trimen I am indebted for the following extract from the Bot. Magazine, which shows that the *Cerasus sphænocarpa* is the Noyau cherry of the West Indies, which in some way, not known to me, has got mixed up in this respect with the *Cerasus occidentalis*:—"In the preparation of *Noyau* probably several different vegetables are employed which contain Prussic acid. A species of Bindweed, the *Convolvulus dissectus*, abounds in Prussic acid, and to that degree as Dr. Nicholson of Antigua informs me, that 'if this medicine shall be found deserving the high character which some physicians have bestowed upon it, it may become valuable in a country where this Prussic acid cannot be preserved many days in a pure state.' Hence this is a frequent ingredient in the preparation of Noyau."—Hook. in B. Mag. t. 3141. *Cerasus sphenocarpa*, Noyau cherry of W. Indies.

From plants of the *Ipomœa sinuata* growing on fences in Union Place, the following notes are given:—Stems, petioles, and lower parts of peduncles covered with long hairs; leaves palmate, glabrous or nearly so, cut down nearly to the centre into seven lanceolate, deeply toothed or pinnatifid lobes; peduncles one to four flowered, and with the flowers together about the same length as the leaves; sepals elliptic, oblong, obtuse with a minute cusp, glabrous, fleshy, inflated before the fruits are ripe, then papery and spreading; flowers shallow, funnel-shaped, about two inches across, white with cerise throats; capsule about half-inch diameter, glabrous, two-celled, normally four-seeded, inflated and divided into four parts; seeds black, glossy, smooth. The flowers begin to open about 10 a. m. in Colombo, and are open nearly the rest of the day.

W. FERGUSON.

CACAO IN MONARAGALA.

Raxawa Estate, Monaragala, 5th July 1884.

DEAR SIR,—Being rather alarmed at what appeared in the *Observer* of the 30th June about cacao-blight, I made a careful inspection of all the cacao here today and I am glad to report that I could find no trace of disease or blight; in fact, I have not seen the cacao looking so well for some time as it is at present. All the trees over two years old have a very good blossom on now. I may mention that we have over fifty acres on this estate; twenty-five acres through coffee, eighteen months to five years old, and a clearing twenty-six acres eighteen months old. I have several times after the monsoon noticed a few trees looking very bare with the ends of the branches black. I am under the impression that this is caused by wind or thinness of soil. Coffee and cacao all over the district are looking very well, and we will do much better this year than we did last. There is over one hundred acres being opened in cacao this season.

The weather since the end of last month has been very pleasant: fine mornings with slight showers in the afternoons.—Yours faithfully,

R. H. C. MACQUARRIE.

DRIED APRICOTS.—California fruit-growers have discovered that apricots bleached with sulphur fumes and then dried in the sun are superior to those that are dried in any other manner, or that are canned. They regard this fact of very great importance to the whole State. It enables every fruit-culturist, however limited his means, and however small the product of his orchards, to dry his own fruit for market, and makes him independent of the canning factories. It is also stated that fruit can be prepared in the same manner more cheaply than in any other, that its weight is better preserved, and that it is of superior flavour. Large dealers in dried fruit say that the market for such products of California orchards will always be greater than the supply can possibly be. The United States alone will readily take all the fruit of the kind and quality now being produced by the sun-drying process that California can ever raise. Many thousands of apricot trees have been planted within a recent date in orchard form in Southern California. Sun-dried apricots are being sold to California dealers at double the price paid for the best raisins.—*Adelaide Observer*.

VALUE OF CACAO PROPERTY.

One of our merchants, Mr. George Fitt (already a successful cacao planter, owning an old cacao property in Chaguane, purchased by him some years ago of the Colonial Company for $12,000, for which today he would not take $100,000), has just become the owner, by purchase, of a couple of adjoining cacao estates in Montserrat, one Tutelar and Esperanza, at present yielding about 150, and the other El Salvador about 300 bags per annum. Being young estates, and situated in a growing quarter, they only want ordinary care with barracks for more labourers and some loose capital, to develop into a more valuable property. For the former Mr. Fitt has paid $20,000 and for the latter $43,200 (£9,000). On the former we understand there are about 18 to 19,000 trees (young, and in bearing), and on the latter about 55,000. The first measures 91 acres, of which about 70 are in cultivation, and some acres under contract to plant cacao, and the second 195a., of which 180a. are cultivated. When the trees are all bearing, they will give 600 bags a year. The trees are usually 12 feet apart. We are informed that the cacao trees on the *Maracas Bay* estate average 3 lb. a tree, about double the mean of other estates taken together. The soil is a rich black *humus*. Upwards of 200 large pods were lately counted on one tree, but some of these may drop or wither before maturity. They seemed to be more than the tree could have the force to mature. It is reported of a fortunate cacao planter of one of the northern districts, who had the luck not many years ago, to invest in a large, old and backward property abounding in rich black soil, that after deducting the losses caused by the hurricane of September 1st, 1878, he cleared the sum of two thousand pounds sterling from the operations of last crop.—*Trinidad Chronicle.*

SHELLAC.

Many of our readers are interested in this singular substance, and we give its manner of manufacture and refining, as gleaned from reliable data, coupled with personal observation.

Ordinary commercial shellac, it is well known, when treated with alcohol does not furnish a clear solution, but always furnishes a more or less turbid, yellowish solution, which, when warmed, clears itself by forming a brown solution and throwing down a grayish-yellowish sediment. Also by filtration through a good thick filter paper, a perfectly clear solution can be obtained, but this succeeds only when there is about ten per cent of shellac in the solution, and not in working in large quantities. Of course there is no difficulty in subsequently concentrating the thin solution by evaporating the access of alcohol, but the filtration of large quantities is attended with loss of time and materials as well as other difficulties, for it is not easy to make the filters tight enough to prevent loss of alcohol, and the filter paper has to be frequently changed.

Dr. Peetz proposed to add finely-pulverized chalk or carbonate of magnesia, which would carry down the light particles of wax that make the solution turbid. This may answer for small quantities, and where the cost of manipulation is not taken into account, but is absolutely useless for large quantities.

Shellac is not a pure natural product, but is prepared from stick lac by melting, straining and washing. Both in stick lac and shellac there is substance which some chemists call wax and others fat, that will not dissolve in alcohol or ether, but is soluble in benzine, naphtha, etc. Dr. Peetz adds to three parts of shellac solution one part petroleum ether and shakes well. After standing quietly for a few minutes the liquid forms two layers; the upper light-brown one is petroleum ether containing the dissolved fat or wax, while below is a clear yellowish brown solution of shellac to which only a little naphtha adheres. On removing the upper layer and allowing it to evaporate spontaneously, a white residue is obtained, consisting of the fat that was in the solution. This fat can be saponified with caustic alkali, but is not dissolved by carbonated alkali, and on this property depends the new process for refining of shellac.

The water is heated to boiling in a suitable kettle, the soda is added next, and when that is dissolved the shellac is put in slowly, waiting for the first portion to dissolve before adding more. The liquid has a pink colour and the well-known agreeable odour of shellac. It is turbid from the small amount of fat in it. After all the shellac is dissolved, the solution is boiled a few months longer, and the kettle covered with a tight-fitting wooden lid, which is luted on with clay, so that no air can enter. It is then allowed to cool slowly, and when the cover is at length removed, a thick cake of fat will be found floating on the liquid.

This is removed and the liquid strained through a linen. The shellac is then precipitated with dilute sulphuric acid added drop by drop. The yellow shellac is washed until it is no longer acid. The well pressed cake is put in boiling water, when it becomes softened, so that it can be worked by the hands into rods, strings or rolls, which are next put in cold water containing glycerine, so that it will harden quickly and then dry.

The hot, soft shellac must be squeezed, wrung and pressed to remove all the water. This refined shellac has a silver white brilliant surface, is yellowish-brown within and must be perfectly dry so as to dissolve without residue in alcohol. The presence of water in alcoholic solutions of any resin makes it turbid and milky.—*Independent Journal.*

COCOA-BUTTER.

The fruit of the cocoa-tree have an oily, more or less bitter taste, which is the consequence of the presence of a species of fat, known as *cocoa-butter*.

As early as 1695 this matter was secreted and described by Homberg in the *Histoire de l' Académie Royale des Sciences.*

The cocoa-nuts contain 12 per cent shell and 88 per cent kernel, which latter consists on an average of one-half oil or grease. The quantity of fat varies with the sort of cocoa-beans; the accompanying table gives the components of two of the best sorts of peeled cocoa:—

	Caracas.	Guaayquil.
Fat	52·20 per cent.	47·85 per cent.
Organic matter	39·00 „	41·50 „
Ash	3·20 „	4·45 „
Water	5·60 „	6·20 „
	100·00 per cent.	100·00 per cent.

In former times the ground and roasted cocoa-beans were boiled with a tenfold-quantity of water, the floating fat was then skimmed off and the rest pressed out. This method is no longer followed. At present the peeled and roasted beans are first ground to a powder, the mass is heated to 70 or 80 degrees Celsius, pressed out between heated plates, and the liquid thus expressed is then filtered. The residue then still contains 10 à 15 per cent of fat, which floats on the surface of the cocoa used for chocolate, and is properly the cause of the slight stomachic discomfort felt by many who drink freely of such chocolate.

Cocoa-butter in its fresh strate is of a yellowish colour; by long standing the colour becomes whiter; it has a sweet agreeable odour, which disappears on boiling with alcohol.

It is remarkable that this fat remains so long good, without turning rancid. Its consistence is pretty hard: the melting point is a little below 30 degrees Celsius, in some sorts, however, at 25 degrees Celsius.

Its specific weight is, at 15 degrees Celsius, between 0·89 and 0·91.

Cocoa-butter consists chiefly of stearic acid and oleic acid, and contains also small proportions of palmitic and arachidic acid. It saponifies very easily. The component parts are:—

Carbon	75·20 per cent.
Hydrogen	11·90 „
Oxygen	12·90 „
	100·00 per cent.

The rather high price of cocoa-butter leads to many adulterations. For this purpose wax, stearine, parafine and suet are mostly made use of. To test the purity or genuineness of the article the observation of the melting point is especially resorted to; this must not be below 25, nor above 30 degrees Celsius. The melting point of cocoa-butter mixed with fatty oils is below 25 degrees; that of

the butter adulterated with the abovementioned matters, above 30 degrees. If one part cocoa-butter be shaken with three parts aether at an ordinary temperature, the pure cocoa-butter will give a perfectly clear solution, while the presence of tallow and wax is betrayed by the liquid remaining turbid, while a white sediment is precipitated. The presence of parafine is marked by a soapy feeling and a diminution of specific gravity.

The addition of stearic acid is as easily to be detected; in the first place the specific gravity increases, while by boiling with diluted soda-lye sodic stearate is formed, which on treatment with sulphuric acid deposits stearic from the fluid.

Cocoa-butter is a by-product in all extensive chocolate works. It is used chiefly for making soap, perfumery and cosmetics, and also for outward medical applications. Its not turning rancid is especially of great value for this latter purpose.—*Indian Mercury.*

MADAR (CALOTROPIS GIGANTEA).

A number of communications have been received from different parts of India regarding this shrub, called forth by Major Johnston's letter published in the last proceedings in which he mentions that the plant is supposed to be an antidote to cobra poison; many correspondents appear to think that the numerous properties of this plant have not previously attracted attention. Yet over 30 years ago the very superior fibre it yields, one of the strongest of the many Indian fibres, attracted the attention of this Society; and its other qualities have been noted. Major Johnston has been asked which of the two species of Calotropis (C. Gigantea and C. Procera) is thought to have special virtue in case of snake bite, his reply will be noted in due course. Meanwhile the following notes kindly furnished by different members may be of interest, being original:—The two species are readily distinguishable by the flower, that of the C. Gigantea being rose or lilac colored and of the C. Procera white. "There are two varieties of the Akhaun (Calotropis Gigantea) growing in this district (Jessore). One of them, the white-flowered variety, called by the natives Seth Akhaun, and the other, the lilac-flowered variety, called by the natives Nela Akhaun, the former of which is used by the natives here in cases of snake bites generally and cobra bites especially—their recipe is as follows:—Take a 2 anna piece weight (⅛th of a tola) of the peel or outer covering of the root of the Seth Akhaun, and half that weight of common ginger. The patient is to chew both the above ingredients together in his mouth, and if they taste sweet it indicates that the virus has entered into the system. In that case he is to chew successive doses of the above medicines until they taste bitter to him, when it shows that the poison has been contracted and that he is free from danger. Of course the patient must swallow the juices of the medicines along with the saliva rejecting the refuse from his mouth. The natives here place implicit faith on this medicine, considering it an infallible cure; but I have little doubt that it has little or no efficacy, like all other reputed antidotes for snake bites for when it *apparently proves* successful it simply arises either from the snake not having injected its poison into the wound, or from the poison-bag being at the time exhausted of its supply; and that such cases sometimes occur will be found from the results of Dr., now Sir Joseph, Fayrer's experiments as noted in his well-known work on the subject. The above plant has many valuable therapeutic properties which are too numerous to detail here; they will be found mentioned in Colonel Drury's useful plants." I may add that it is one of the strongest fibre-yielding plants, but owing to its not thriving under cultivation, it is not able to be utilized to any appreciable extent."

"The medicinal properties of this plant have been pretty fully described by Dr. Kanilal Dey in his indigenous drugs of India, by Dr. Udoy Chand Dutt in his Materia Medica of the Hindoos, by Dr. Waring in his bazaar medicines and by other writers. The various parts of this plant not only form important elements in several standard Hindoo medicines, but they are also very largely used by the people of this country as domestic medicines. There are two varieties of the Madar plant,—the red flowering and the white flowering. Both the varieties are useful in leprosy, carbuncle, enlarged spleen, &c. The white variety is said to be a good appetiser, digestive and a curative of cough and asthma. The red variety is said to be good in colds and in inflamatory diseases, looseness of bowels, lepra, worms, skin-diseases, dropsy, and in enlarged abdominal viscera. The *flowers* are used as a tonic appetiser, and digestive. The *bark* of the root is used in cough, asthma, dysentry, diarrhœa, skin-diseases and inflamatory diseases. It is said to be a good substitute for Epicacuanha. In 12 to 15 grain doses it is used as an emetic and in 2 to 5 grains it is used as a Diaphoretic. The *leaves* mixed with rock salt and roasted within a closed vessel are widely administered in enlarged spleen. The milky *juice* is used as a purgative and also as a sedative in toothache and caries. In Sphilis and mercurial disease the milky juice of the plant and also the inspissated juice of the leaves are held in great esteem and are widely used with unvarying success."

"Kindly enquire of Major Johnston, of Metapolliam, if it is the juice of the white or the purple flowering Madar which is the specific for cobra snake bite. We have both descriptions in this district: the natives prefer using the leaves of the white for rheumatic pains and the juice of the white in leprosy."—*From Proceedings of Agri-Horticultural Society of India.*

EXHALATION OF OZONE BY FLOWERING PLANTS.

The question, "Are plants in bedrooms unhealthy or not?" has been frequently put, and as frequently answered in directly contradictory terms. The question, so far as the production of carbonic acid is concerned, is of little moment, for the quantity of that gas given off during a night by any conceivable number of plants likely to be placed in a bedroom is so small as to be practically harmless. It is the organic matter which accompanies the expired breath of the sleepers that really renders the air of a bedroom foul, and it would seem from some researches made by Dr. J. M. Anders that flowering plants at least help to purify the atmosphere wherever they may be placed. Schreiber and other investigators have, for instance, asserted that the emanations from Pine forests actually convert the oxygen of the air into ozone, and Naquet goes further with the dictum that "ozone exists in woods and fields, and wherever there is active vegetation." However ozone may be produced, there seems no difference of opinion as to its value in our atmosphere, for the majority of chemists are agreed that it is the "great purifier," and no one can attribute any deleterious influence to it. Ozone is rarely found in dwelling-rooms, as it is decomposed in the process of oxidising the organic matter present, and it is only when a number of flowering plants are introduced that ozone in any appreciable quantity can be detected. Dr. Anders has, during the last three or four years, devoted much of his leisure time to an investigation of the question whether flowering plants exhale ozone, and in 1882 he commenced a series of experiments in the Horticultural Hall of Fairmount Park, Philadelphia, which have enabled him to answer definitely and decidedly in the affirmative. In an interesting review of the subject, which he has contributed to some recent numbers of the *American Naturalist*, he leaves to the expert chemist the determination of the real nature and properties of ozone, and proceeds to explain how he has discovered that it is exhaled from flowering plants. It was thought at one time that the green parts of plants evolved ozone under the influence of the sun; but lately it has been accepted, principally on the evidence of Cloez and Bellucci, that the change in the iodised test-paper, supposed to be due to ozone, is really caused by the action of moisture, oxygen and light. The first experiments of Dr. Anders were made in the main hall of the buildings at Fairmount Park, which is 220 feet long, 100 feet wide, with curvilinear roofs. 65 feet high in the centre. This house corresponds to what is known as the Palm-house at Kew, and is filled with similar plants, the average temperature being 70° Fahr. Alongside is the Fern-house, the forcing-house, the temperate-house, the propagating-house, and the economic-house, each about 100 feet by 30 feet by 20 feet. Many of the first tests were negative, amongst other reasons because the houses were daily visited by considerable numbers, and the ozone, assuming any to have been present,

would be used up in oxidising the organic matter given off from the lungs of the visitors. The next series of experiments were commenced in February, during which month only an occasional visitor was admitted, and the chief result was that in the propagating-house the action was found to be greater than in the external air, though even then the coloration was marked as "very slight." He obtained positive evidence that flowering plants atany rate exhale ozone, and it became necessary to repeat the experiments out-of-doors, and to ascertain whether the reactions indicated by the test-papers were really caused by ozone. Accordingly a plant case was removed to the "back yard," where the plants received the sunshine for at least eight hours daily during clear weather, and gave still stronger evidence of their power in colouring the test-papers, probably because the situation was better calculated to enable them to exert their influence, and also because the experiments were of longer duration. A piece of red litmus suspended in the case gave no indication of the presence of ammonia, and peroxide of hydrogen could have nothing to do with the effects observed on the test-papers, because the temperature of the air within the case, which was carefully noted, was never found less than 90°, or 20° higher than the point at which peroxide of hydrogen is decomposed. Dr. Anders satisfied himself by several repeated tests that the reactions were not due to nitrous oxides, and that being the case, the conclusion is inevitable that flowering plants exhale ozone. A trial with foliage plants having soft thin leaves gave negative results. Seven plants of what Dr. Anders calls asperdisteus (probably Aspidistra), one Fern, and three Dracænas were placed in the case for a week, the weather being extremely warm, the temperature of the air in the case ranging from 85° to 100° Fahr. The Schönbein papers gave negative results throughout, and those prepared with guaiacum gave one "very slight reaction." As the first experiment with what Dr. Anders calls inodorous plants did not yield any very definite results, a further trial with seventeen healthy Pelargoniums was made for six days, the observations being taken during ten hours on each day. The Schönbeins gave one negative, and two "slight," three "marked" blue shades, the negative result occurring on a rainy day when there was no sunshine whatever. Further observations were made on these plants with similar results, and the conclusion again is inevitable, that flowering plants, even when inodorous, exhale ozone. The experiments also prove that sunshine, or at least strong diffused sunlight, is as essential to the generation of ozone by plants as it is to the work of assimilation and transpiration carried on by them.—*English Mechanic.*

THE OODEYPORE GARDENS.

Mr. T. H. Storey, the Superintendent, has issued the following Report for 1883, on the Gardens of H. H. the Maharana of Oodeypore, G.C.S.I.:—

The Gardens are situated in a valley bounded on the south by a large hill over which the city wall runs and dips into the lake on the west side. The hill is very grand, towering above the gardens and clothed with thick jungle which during the rains is very imposing. The only specimens worth noticing on it are Hemidesmus indicus or Indian Sarsaparilla, Adiantum Capillus Veneris and Actinopteris Radiata. On the north lies one of the most beautiful lakes in the plains of India which gives an endless supply of water to the gardens and is about 80 ft. above its level, kept back by natural rocks and a bund. The Palace lies to the North side also and commands a fine view, not only of the gardens and city but the lake plains and hills for miles around. The gardens round the palace are very beautiful; plants are growing in rustic baskets made of glass, marble and china, and meet the eye on every side. There are also to be seen garden seats, flower stands and tanks made of fine white marble in which swans made of the same material are gracefully swimming about. A great part of the lake can be seen from the palace windows, where you can always get, on the hottest day, a fine cool breeze. In the centre of the lake and about half a mile apart are two islands palaces which vie with each other in beauty. The one nearest the palace has got a lovely garden containing a number of orange trees of the finest description and bearing fruit of the finest flavour. On the opposite side of the lake are acres of Lotus, Nelumbium Speciosum which flower during the hot season; some of the leaves appearing like miniature Victoria Regias. The flowers are also much larger than than any I've ever seen before; some of them measuring one foot in diameter. The only other aquatic plants found in the lake are Vallisneria spiralis, Pistia Stratiotes [or water soldier] and Anacharis Alsinastrum, and as the latter is supposed to an American plant, it seems a mystery how it found its way to an inland lake without any connection or river. It is well known in England as it obstructs boating in canals and lakes and is commonly known by the name of swan weed. I arrived at Oodeypore in January and took charge of the Gardens, which had up to that time been managed by Mr. Umbaoji, the native Engineer in charge of H. H.'s buildings. But the actual garden work was carried out by Fatteh Singh, Head Gardener, who came from the Government Botanical Gardens, Sabaranpore. The first work which I commenced was a carriage drive from the centre to the east side, but owing to want of material was obliged to abandon it for some time. I then commenced a plot of ground at the back of a little palace at the south side of the gardens with a view of laying it out as a flower garden. I had it dug two feet deep, all stones picked and the ground levelled, manured and planted with Cynodon dactylon [Hurryalee grass] roots, cut out handsome flower beds of different shapes and planted them with annuals and also made a rockery in front of the palace which improved the place very much. We then commenced planting grass on either side of the drive, which took a little over a month to complete. The greater part of the drive was made with mortar and rubbish from an old temple alongside it which took a long time to clear away, after which we made a temporary nursery for surplus trees and shrubs and also a large plot of ground for hot weather vegetables, which took almost a month to complete. On H. H.'s coming to the gardens and consulting with me as to what should be done with the whole plot over an acre in extent, it was decided to lay it out as a cricket and tennis grounds. The whole plot, with the exception of the vegetable ground, was a complete jungle of useless fruit trees and shrubs, and took a long time to clear away. This being done, the land was ploughed and made quite level and the whole planted with hurryalee grass roots and ornamental trees. Two clumps of foliage and flowering shrubs were also put down, leaving a place for sitting in the centre. H. H. was very much pleased with the plot when finished. The grass was collected from different parts of the garden and planted at a trifling cost. Though unsightly at first, it soon became quite as good as turf brought from the opposite side of the lake.

The next work of any importance was slopping the sides of the carriage drive and making a curved road leading up to the bird house. After finishing the road we began the other side of the cricket ground about an acre in extent. The whole plot when finished and rolled looked very well.

As the rose plants were scattered in all parts of the gardens, and it was very hard to look after them, H. H. decided on making a new rose garden to the right of the present main drive. The plot of ground selected for it was very uneven and full of stones, which gave much trouble to clear off. To bring the soil from the foot of the hill for filling up the holes, would have cost an immense deal, so I decided on making a pond in the centre to enable me to get sufficient soil to level off all the plot and make it suitable for roses. The soil has been washed down from the hill for generations past and is very rich, so that a more suitable place could not have been found. H. H. expressed a wish to have three or four coloured roses on each standard, which was carried out very successfully, and when in flower had a very pleasing effect. The kind of roses used for standard was Edouard which seems to be the best I know of for working on. The buds took very well. We got a collection of named varieties from the Taj Garden, Agra, but on their coming into flower many of them were not true to name; for instance some marked white turned out red. The ground took a long time to get into order, owing to stones, holes and jungle. The pond in it looks very well and is intended for Victoria Regia. I got ten Victoria seeds from Joseph

Steavenson, Esq., Hon. Sec., Agri-Horticultural Society's Gardens, Madras, an institution every possessor of a garden should become a member of. I hope to get H. H. to become a life member. Apart from the valuable information you get sufficient seeds for an ordinary garden. The seeds were carefully sown in a pot and submerged in a large oak tub, but up to the end of the year, I very much regret to say, they did not germinate, although keeping quite fresh.

H. H. was anxious to have a separate fruit garden situated in a suitable part. We selected a large plot of about six acres in extent at the south side of the gardens and commenced by planting 200 grafted mangoes received from Agri-Horticultural Society's Gardens, Madras. The plants were despatched in charge of an experienced gardener, and notwithstanding the great distance by rail and road, they arrived in excellent condition. Only one plant out of the lot reached in a sickly state, and eventually died; showing the attention and care taken of them on the road. The following are the names of the plants:—Peter Dilpasand, Romnie and Guava. They were all planted in a large tope with the exception of four or five H. H. had ordered to be planted at the palace, and as there were no grafted mangoes in Meywar, H. H. wished to introduce superior kinds, which will bring a handsome revenue in two or three years, and will be one of the most handsome mango topes in all Rajputana. The gardens contain a large and handsome collection of plants, a good number of them being brought from Madras, Bangalore, Saharanpore and other places. I cannot pass over without mentioning the beautiful peacocks that daily frequent the gardens in hundreds, H. H. ordering maunds of grain to be kept and given to them every morning. Although they are very destructive to vegetables and flowers, &c., their beauty compels us to overlook their destructive habits.

The band stand is situated almost in the centre of the gardens, and is a little checked up with trees and flowering shrubs at present, and as that part of the garden will be altered, this will be remedied. The band plays every Monday evening, and it is to be regretted the inhabitants of the station don't patronize and encourage the bandsmen by their presence. They often play only to the surrounding scenery and myself. I am glad to say the attendance of late has been much better, as the band is a very fine one. It is well deserving of patronage. —*Madras Mail.*

WATTLE CULTIVATION AS AN INDUSTRY.

[BY ACACIA.]

It is no exaggeration to say that the various kinds of acacia usually spoken of under the general term of wattles form one of the most valuable of the natural products of Australian soil. The bark of these trees has for years occupied an important position in the tanning industry, and it may safely be said that the estimation in which it is held is on the increase rather than declining. Side by side with this fact is the important and somewhat distressing circumstance that the yield of bark appears not only to be on the decrease in quantity but also in quality. The reason of this falling-off is not far to seek. In the early days of wattle-stripping the procuration of sufficient bark to meet all requirements was accomplished with comparative ease, inasmuch as wattles were to be found growing here, there, and everywhere. So widespread was the natural habitat of the various sorts of acacias in South Australia that, within the settled districts at all events, it is more difficult to define localities where it did not and would not grow than to name localities where it would and did thrive. A very large proportion of the unalienated lands was more or less covered with wattles, and so great was the area that strippers could find a great deal more bark than they had time to strip. Gradually, however, as these lands were parted with by the Crown, the natural growth was burnt off to make way for sheep or wheat until, as is now the case, wattles are considerably reduced numerically, and are only to be found in certain portions of the original area. As a result of this reduction the price of bark went up to a high figure, and the occupation of stripping and selling bark has now become such a profitable one that strippers pursue their avocation without the smallest discrimination whatever, utterly regardless of the state of the bark when gathered and quite oblivious to the future supply. Every available wattle-tree within easy distance of a commercial centre is denuded of its bark, and by this wholesale destruction thousands of young trees of perhaps not more than three or four years' growth are cut off before their prime. Such sinful waste cannot be too severely condemned. The bark from these young trees is much inferior in quality to those of mature growth, while the presence of so much juvenile bark in the market, mixed as it usually is with that of better quality, must necessarily tend to lower the value of the whole product in the estimation of the tanning industry. Moreover, it is in the primary stages that the growth of this tree is slowest and the accumulation of tannin at its minimum. As the tree advances in years the proportional growth per annum gradually but surely increases both in bulk as well as in the production of tannin. Such facts as these should be lost sight of by all who are fortunate enough to possess natural wattle plantations, and should deter them from permitting any premature stripping on their estates. The time has now arrived when the systematic preservation and cultivation of wattles as an industry will be attended with most profitable results —results which I firmly believe will place wattle-growing in the front rank of colonial industries from a lucrative point of view.

Of the acacias which produce the wattle or mimosa bark of commerce there are two species which stand pre-eminent in this colony. These are Acacia pycnantha and Acacia decurrens. The habitat of the former ranges chiefly from the Adelaide hills north as far as Beltana. North of Spalding, however, this species assumes a somewhat stunted form compared with what we are accustomed to see in the Adelaide hills. The leaves of this variety are also narrower or more lanceolate than those of the typical form, and the whole tree is easily recognisable from its stem and branches being usually covered with a hoary or glaucous substance. North of the position indicated the tree is generally confined to the more elevated and hilly portions of the colony. The typical form is to be found all along the Mount Lofty chain of hills and the plains from Encounter Bay to north beyond Barossa, while specimens are to be met with on Kangaroo Island. The other species named, commonly known as the black wattle, is chiefly confined to the south-eastern portions of the colony. The broad-leaved wattle seldom attains a height of more than 25 feet, with a diameter of 8 inches, although in Brown's "Forest Flora" it is stated that a tree was felled at the Semaphore lately, 35 feet in height and 18 inches in diameter. Acacia decurrens grows to a large tree in the South-East, and may there often be met with over 40 feet in height and 2 feet in diameter. The average yield of bark of the broad-leaf may be put down at about 70 lb. for full, well-grown trees, 7 to 8 years of age; while it is not an uncommon thing to get 500 lb. from the black wattle of a similar age. Although the pycnantha is a smaller tree than the other and is generally less rapid in growth, its bulk is of greater commercial value, owing to its yielding a larger percentage of tannic acid than the black. The pycnantha on an average yields about 35 per cent of tannic acid, sometimes as much as 40 per cent, while the Acacia decurrens rarely gives more than 25 per cent. The logical inference therefore points towards Acacia decurrens as the most profitable for cultivation, as in spite of the lower yield of tannic acid per ton, this disadvantage is fully met by the increased yield per acre. Both trees grow readily in almost any soil, although they seem to have a preference for those of a sandy nature on surface, supported by a good yellow clay subsoil. When grown upon pure sand the bark is somewhat deficient in tannic acid, being at the same time of a thin nature and too full of sap to pay well for stripping. It is worthy of note that bark stripped from trees which have been grown upon poor stony ground produces the greatest percentage of tannic acid. This is a fact of great importance, as there is an immense area of country in this colony of this nature that has hitherto been classified as unproductive land, but which might with great profit be utilized in the production of these trees.

Both species attain their prime condition between the ages of six and ten years, according to locality and quality

of soil. When they are grown on the sandy soil, *i.e.*, with clay bottom, they come in for stripping about the sixth year, while on the stony ground it may safely be asserted that the trees would not mature and pay—"pay" meaning the fullest return obtainable from the tree—to strip before the eighth year. Attention may have been called to the immense amount of pigface country along our southern coastline on the one hand, and the numbers of rocky patches scattered over the inland country, both of which are suitable for profitable wattle growing. Touching the methods of cultivation, sandy soil being of a loose nature, the crop should be put in with the plough by ploughing strips eighteen inches broad and four feet apart to a depth of about four inches. The seed should then be dropped in about three feet apart along the rows. For the first two years after the crop has been sown the ground betwixt the rows should be regularly ploughed or scarified, for the more the land is stirred the more moisture will find its way to the roots, ensuring quicker growth, while ploughing will at all times prove a very valuable ally against fire. The latter item is worthy of note, for I believe I am correct in saying that the various insurance offices do not accept wattle risks although far safer than the wheat crops so readily accepted. By adopting this method of cultivation it is calculated that at least two years will be saved in the maturing of the plants than if left to Dame Nature. About the second year pruning must be taken in hand. The rows should be taken in hand systematically, and all large lateral branches which may appear to be interfering with the upward growth of the plant should come off. This operation should be repeated during the third year, after which the trees, partly from the effect of this operation and partly by their proximity to one another, will attain that straight upward tendency of growth which must necessarily be regarded as one of the principal features of a successful wattle plantation, because it is only from straight trees that the bark can be removed with facility, and as a natural consequence the price payable for stripping reduced to its lowest ebb. It may be here noted that the bark which produces the greatest percentage of tannic acid is that which grows on the stem of the tree, and therefore the system of cultivation should be directed to produce as large a bulk of stem as possible, with the least amount of liberal growth in the shape of branches as is consistent with the proper health of the trees. This can only be obtained by thick planting in the first instance, and early pruning as above indicated in the second place. From careful experiments made it has been ascertained beyond doubt that at least 25 per cent more of tannic acid can be procured from a well-pruned tree than from one left to its own devices, involving that branchy growth which is one of the principal characteristics of the tree.

In the method of planting indicated above, planting at a distance of four feet apart has been advocated, but I must here state that many authorities, among whom I may mention the Conservator of Forests, advocate planting at a distance of eight feet apart in the first instance, and filling up between these rows at the end of the third year. Of course, as wattle cultivation is a thing of the future, experience only can decide on what is at present an open question.

On rocky soil, of course, the same method of cultivation cannot be followed that is feasible on that of a sandy nature, and it is necessary to substitute the spade for the plough. This is, of course, assuming the soil to be of a hard nature. If, however, the soil is of a loose nature it will be found sufficient to sow the seed broadcast after a heavy fall of rain, and the success will be all the more assured if a flock of sheep be run over the area four or five times. This plan has been successfully carried out by the Forest Department in the South-East at Mount Burr. The next item of importance is the preparation of seed. When this is intended to be covered, either in ploughed ground or by the spade, the plan of scalding the seed has been found to answer the purpose admirably. The simplest way of scalding the seed is to pour almost boiling water upon it. The seed should then be left to soak for about forty-eight hours, and afterwards sweated in a damp bag until quite soft. For broadcast sowing on the surface, however, this does not give good results, because the seed being half-germinated a change of the weather to dryness is sure to result in a stoppage in germination, and consequently, from want of moisture, causes the young shoots to "damp-off," and the seed decays. In order to obviate this, and prepare the seed all ready for germination in such a manner that it will be independent of any sort of weather, the plan has been adopted of cracking the outer hard covering of the seed by the means of slow firing without partial germination, so that the seed can be sown upon the ground, and lie there without injury until sufficient rain falls to make it germinate. In this manner the seed can be sown two or three months before winter, and thus will be in readiness to benefit by the first rains of the season, and consequently the young plants will, before the rainy season is over, have attained such a hold upon the ground that their safety is secured during the following dry season. An explanation of the system adopted will be *apropos*. A high heap of wood is formed and fired; when this has smouldered down to a common expiring condition of red coals and ashes, the seed is thrown into the heap and the whole stirred up and allowed to remain until the fire goes out. The embers are then raked in a heap, and the ashes and seed bagged together ready for sowing broadcast. There is no doubt that this system is only following out what we see in nature, as all colonists have no doubt noticed that when branches or débris of a wattle-tree have been burned, numerous young trees spring up as a matter of course. Following out this system, it is only necessary when indigenous wattle plantations are conserved to burn up the branches of the trees which have been stripped in order to secure a luxuriant young crop. This method has been successfully carried out at the Mount Brown Forest Reserve.

From recent analyses it appears that although the bark upon the trunk of the tree produces the largest percentage of tannic acid, that upon the branches and twigs, as well as the leaves themselves, and to a certain extent the wood of the tree, contain a fair percentage of tannin. In some cases a greater percentage of tannic acid was obtained from the twigs and branches than is procurable from the best English oakbark (which, by the way, is very difficult to strip). This fact opens a question. Cannot we utilize the tannic acid which, under the present system, is allowed to go to waste on the ground? It is well known to all colonists that hitherto strippers of this bark seldom or never attempt to remove it from the branches, and it has been calculated that in consequence of this, of every one which has been or is being stripped, at least one-third of its tannic acid has been allowed to go to waste. Looking at this fact then, and also bearing in mind that however well the trees may be cultivated and primed under the system recommended, there must always be a considerable quantity of branches and leaves, it is thought that when the wattle is cultivated as a commercial crop some means should be adopted whereby the tannic acid in this débris could be utilized, and the idea has been broached that this might be effected by a boiling-down system. Huge tanks could be constructed, into which every portion of the tree could be placed after being chopped up, and the tannic acid extracted. The plan seems feasible enough, and if it can be profitably carried out as suggested, possibly it could be improved on so as to place the tree in whole without any chopping whatever. Enormous saving from its adoption must necessarily ensue; less cost than stripping, in the first place; considerable economy in carting to market; less bulk for export; no loss from pruning. In addition to these advantages the pap would eventually come in either for paper-making or manure. As, however, this plan has not yet been adopted, I cannot submit figures in a balance-sheet. Before submitting an estimate on the probable results of wattle cultivation as an industry, I would like to refer to two pamphlets on the subject already in print. One of these is termed "Wattle Bark," and is substantially a report of the Board of Enquiry appointed in Victoria; the other is termed "Wattle Farming," and is written by Dr. Schomburgk, and published by the Chamber of Manufactures. The former is devoted almost entirely to the rise and progress of the wattle-bark trade of Victoria, and the evidence of some two hundred witnesses who were examined. Into this I will not dip, but an appendix to the work gives a statement showing the profit to be derived from the systematic cultivation of wattles compiled as a result of the enquiries instituted,

which deserves attention. I do not for a moment wish to damp the enthusiasm of advocates of wattle cultivation, but I would point out:—

1.—That if the production of wattle-bark varies between two given numbers per acre, it is safer in estimating to take the lowest and thus be prepared for casualty.

2.—That although there is every reason to believe that "cultivated" wattles could be stripped for at least half the amount paid for stripping those which have been left to nature, still there is reason to doubt whether strippers at the present time make really good wages at the work, and the reduction that would ensue is, therefore, problematical.

The Wattle Commission and Dr. Schomburgk show a profit of over £2,000 per 100 acres in a run of eight years, and arrive at this highly desirable conclusion by estimating a return of 1,213 tons of bark from those 100 acres. On the other hand stripping is estimated at 15s. per ton as against 30s. now actually paid in this colony, while cartage is put down at 10s. per ton, which, at the present price of wages, I consider, with all due deference, to be at least 30 per cent below the probable expenditure.

As selectors in this colony are permitted to take up 1,000 acres, I have chosen that area for my calculations, and this, according to the Wattle Commission, would yield over 12,000 tons, whereas I put it down at 5,000 so as to be on the safe side. With regard to pruning the Commission estimate 10s. per acre as against my 4s., and this is the only item in which my figures come under those of the Commission and Dr. Schomburgk. I am of opinion that the item *might* be left out entirely, as the Manager would almost as a matter of course take this into his own hands, and his salary is schedided. Attention is called to the following facts:—

1.—The bark from the broad-leaved wattle is the best in the world; that from the black wattle the second best.

2.—The price of bark is rising, and good material is so scarce that a quantity of inferior bark is used by European tanners out of sheer necessity.

3.—Land that will grow wattles successfully is not at present looked upon as worth £4 per acre, the amount set down in the following estimate:—

Estimate of Expenditure on a Wattle Plantation of 1,000 Acres, Valued at £4,000, for Six Years.

Interest on freehold, + compound thereon ...	£2,150
Ploughing and sowing, at 10s per acre, + interest	835
Pruning second and third years, at 4s. per acre, for the two years, + interest ...	291
Scarifyiug twice, + interest, say	500
Unforeseen expenses, say	100
Cartage to market and stripping, at £1 and £1 10s. respectively	12,500
Supervision	860
Balance of profit over and above good commercial return for capital throughout ...	7,764
Total	£25,000

Receipts.

Sale of 5,000 tons bark, at £5	£25,000

It will be seen that no credit has been taken for the gum procurable from the plantation, nor for seed. Again, the price of bark has been set down at £5, while it is being sold for considerably over £7 at the present time, and in six years' time must fetch more. There were sales in London of chopped bark at £17 per ton recently. Some believers in wattle-growing advocate sheep being run over the plantations after the first two years, but there are two objections to this, viz., if the ground be thoroughly planted there will be very little grass, and that of an inferior character; and secondly, this plan would interfere with the natural regeneration, involving resowing and consequent delay. If the plantation be devoted to wattles, and wattles only, a crop may be relied on every third year after the first six. Yet another point to be remembered. The galls growing on the trees are of considerable value, and could be most profitably utilized on large plantations.

Note.—The above article has been read by me, and I can confidently endorse the general remarks, while I consider that the probable profits shown in the balance-sheet are in no way over estimated.—J. E. Brown, Conservator of Forests.—*Adelaide Observer.*

Olives are as easily raised from cuttings as grapes. The slips are usually set in a sandy soil. The cuttings used by Americans are a little more than a foot long; but it is said that the Spanish people sometimes plant great branches, 10 ft. or so in length, packed round about with clay. Such branches as these will bear in two years from the time of planting.—*Queenslander.*

Tahiti.—The *Industriel Français* calls attention to the natural and climatic advantages which are enjoyed by the above island, the connection between which and France is a feature in the scheme of French acquisitions in the Pacific. For many years business was to a great extent monopolised by a few houses, but competition has now greatly increased, with the result of a diminution in the profits of trading. Special importance is attached to the position Tahiti will probably attain in the future, when the Panama Canal is completed, and the efforts of the French Government and of the mercantile community have succeeded in obtaining for French commerce a higher position than it now holds amongst the general trade of European nations in the Pacific waters. The necessity of improved harbour accommodation at Tahiti is likewise dwelt upon.—*Journal of the Society of Arts.*

Tropical Products in Queensland.—A correspondent of the *Port Douglas Chronicle* gives a very interesting account of a garden on the Mosman River, the property of Mr. Dan Hart. Here the writer obtained a cup of coffee "far and away" the best he had tasted since leaving Ceylon, and which was made from berries grown on the place. He adds: "the growth of such trees as Mango, Cinnamon, Nutmeg and Lichee staggered me. I never saw their superior. The Orange, of all kinds, Shaddock and Pomelo trees grunt again under their fruit-burden. The sample of cinnamon shown me was a fine, clean, full-scented bark, greatly superior to the stale stuff imported. The sugar-cane had evidently mastered Dan, the growth being too rapid to get the attention required." Slowly, but we believe surely, our northern districts are being utilised for the growth of various descriptions of tropical products, which will yet become of immense value.—*Planter and Farmer.*

The *Weekly Drug News* of New York, in referring to the process recently described by Professor Redwood for the exhaustion of cinchona bark, speaks of it with approval as a step towards the standardizing of pharmaceutical preparations and as yielding "an elegant extract which has the great advantage of bearing dilution with water without precipitation." But it points out that this desirable quality of water solubility is secured by the elimination of the "peculiar extractive, chiefly quinovin," and demurs to the assumption, in the present state of our therapeutic knowledge, that this "quinovin" has no medicinal value. Against the reference made by Professor Redwood to Mr. Howard's opinion, it quotes a passage from Professor Flückiger's recent work, 'The Cinchona Barks Pharmacognostically Considered,' to the effect that "chinovin participates in the medicinal activity of cinchona barks." Moreover, the *Weekly Drug News* thinks that "if elegance and water solubility are the objects to be attained, the alkaloids may be employed in preference to the bark."—*Pharmaceutical Journal.*

Green Manuring is worthy of more frequent use than is at present attempted. It is Nature's own method of stimulating plant growth, and should commend itself to those who are unfavourably situated or circumstanced for obtaining a supply of a good fertiliser to keep their lands in good heart. The principle that needs to be borne in mind, for success to be realised, is to sow some crop suited to the soil, locality, or climate, which will make rapid growth. In cool climates the lupin is a favourite for the purpose, and, in some instances, buckwheat is used. In special cases, such as where wheat is to follow, it has been found extremely useful as a preventive to rust to sow down with mustard and plough it under as a green manure, the pungent or other properties of the mustard being found more or less a hindrance to the growth of rust. Whatever may be thought about this method of manuring, it is worthy of serious thought that Nature knows little or nothing of any other, and land increases in fertility, and consequently in productiveness, wherever it is adopted.—*Queenslander.*

MARKET RATES FOR OLD AND NEW PRODUCTS.

(From Lewis & Peat's London Price Current, July 3rd, 1884.)

IMPORTED FROM MALABAR COAST, COCHIN, CEYLON, MADRAS, &c.	QUALITY.	QUOTATIONS.

CEYLON PRODUCE AND ITS ENEMIES.

We have received from the Government of Madras a very valuable paper containing full statistics of the coffee and tea cultivation in that Presidency for the year 1883. It commences with the following

Resolution—dated 17th May 1884, No. 1681.

The accompanying statements of coffee and tea cultivation for the calendar year 1883 are submitted to Government for transmission to the Government of India.

2. The resident of Travancore states that the returns of coffee cultivation for the estates of Pathmanapuram, Shencottah, Neyathankari and Kotankarai and Kotankaray have not been received though repeatedly called for. No statistics have been furnished for the tea estate of Thovalay also. The resident has been requested to supply the omission, and to explain the decrease of 50 acres in the area under mature plants against Velavenkode and a corresponding increase in the area taken up for planting but not yet planted as compared with the figures entered for 1882. Supplemental statements will be submitted on receipt of the information called for from the resident.

We cannot afford space to take over the whole of the suggestive figures, but we may mention the chief of them. We find under "Coffee" that the Nilgiris have 459 plantations with an average elevation of 3,000 to 6,000 ft.: these contain 19,786 acres of mature, and 3,111 acres of immature plants yielding 7,085,391 lb., or at the rate of 358 lb. per acre of mature plants. The increase, it is stated is due to several estates in South-east Wynaad and on the Nilgiri plateau having been newly brought to account. Under Madura we see that in 3,355 plantations there are only 3,601 acres of mature plants. This is accounted for by the fact that all patches of native coffee are included, however small. Opposite Ambāsamudram is the note: "Eight plantations have been left waste owing to the failure of crops last year." Against the Wynaad the note is:—"The collector says that he cannot explain the large increase in the yield as compared with 1882, but believes that the managers of the estates are unwilling to give accurate information." For Kasaragod, South Kanara, the cost of cultivation was only RS (per acre), and the remark on this is: "The collector says the low cost is due to the desultory cultivation on the plains, which is not carried on systematically." In Changanacherry, Travancore there are 24 acres of immature plants, and the reason given is that 250 acres had died out: 100 acres had been planted with cinchona. For Thovalay the elevations differed from those reported the previous year, but the Resident had furnished no explanation.

Under the statement illustrative of the state of tea cultivation we see that in Vizagapatam there was only 1·5 acre of immature plants, but 40 more acres had been taken up for planting. In Madura with an elevation of 7,000 feet the acreage is 2·25 of old and 1 of young plants, giving a total yield of 200 lb., or at the rate of 89 lb. to the (mature) acre. The Nilgiris of course show the largest figures for acreage and yield. From 78 plantations, 3,000 to 7,000 feet, containing 3,322 acres mature, and 1,450 acres immature plants, the total yield was 510,280 lb., or at the rate of 154 lb. per (mature) acre: the cost of manufacture per lb. in the province being put at 1½ to 4 annas! We may mention that the yield of tea is placed under the two headings, *Black* and *Green*, and the note is:—"The returns from planters do not in some cases specify the yield of tea under black and green. In such cases the yield is included in the total." Evidently the supposition is that black and green teas are produced from different varieties of plants. In Malabar 62 acres (mature) gave 1,860 lb. or 30 lb. per acre. Travancore possesses 26 plantations containing 137 acres old and 443·5 acres young plants (and 425 more have been taken up for planting), giving 17,150 lb. tea, or 160 lb. per (mature) acre: the cost of manufacture being 5 annas per lb.

With regard to pests injurious to our planting interests here, we were amused to find in the *North-China Herald*, of all papers in the world, the following most interesting account of the green fly:—

Yesterday I observed the branches of a young plum tree in possession of the green fly. Most of the leaves fully occupied were reflexed backwards, so that the midrib of the leaf was the highest portion of it, thus forming a remarkable umbrella under which the heaviest rain would not penetrate. Several leaves I cut off and threw into a large bowl half filled with water. The inhabited portion of the leaf showed a strange antipathy to the water, refusing to touch it when the water was on a considerably higher level. A leaf was immersed and every green fly was immediately covered with a shining, glistening canopy such as I have seen on the water spider when under the water. When the leaf was drawn out the insects were as dry as before they went in. When a large drop of water was poured into the hollow leaf over the insects, it was immediately covered over with a mealy substance, which stood out over the mid-rib like a sparrow's egg, refusing absolutely to touch the sides of the leaf; on touching it with the tip of my knife, the dusty water immediately stuck to it and would not go back, while the insects remained as dry as if no water had ever been near their abode. A large number of populous leaves were left in the bowl all night, and are in it still fully more than 24 hours, the insects being still as dry as when they hung on the tree. A very few, which had dropped off the leaf, were dead or benumbed a short time ago, but the rest are apparently resolved never to drown. The green fly is covered all over with a mealy substance after the fashion of the flower called the "dusty miller." This dusty substance seems to be its safeguard against damp, and a most remarkable safeguard it is, a little sac of air being formed as soon as water touches it, making the glistening shelter which saves the insect from drowning. While under water, th insect moves its feet freely, but rarely raises its head from off the leaf in which its teeth are inserted.

It is a bad look-out for cacao and tea, if our little enemy is really as tenacious of life as the above asserts. On an unknown insect pest we cull the following from the proceedings of the Horticultural Society of India:—

From Messrs. Begg, Dunlop & Co.:—

"We send you a bottle containing some diseased tea leaves and shoots, which we have received from our Manager at Koomber, Cachar, and which we shall be much obliged by your having carefully examined, with a view to ascertaining what the blight is that appears on them. Our Manager says he has enclosed in the bottle what he thinks may turn out to be the eggs of the insect, and should this be the case, he hopes something may be suggested by which to check the pest.

"Should you not succeed in tracing the insect, we are requested to send the bottle home, so kindly send it back to us after inspection."

The Deputy Secretary called on Mr. Wood-Mason of the Indian Museum with the specimens, who kindly promised to give the matter his early attention. Mr. Wood-Mason's letter on the subject is as follows:—

"Three or four of the leaves and the piece of the

stick contained in the bottle you left with me this morning, bear small patches of eggs of some Homopterous insect. The eggs appear to be always regularly arranged. I have met with them frequently on tea-bushes, to which I could never satisfy myself that they did any harm. I believe they are the eggs of an insect closely allied to, and about the same size as the little green flies which are such a pest in the rains in Calcutta. I should be glad if your correspondent would send me some of the flies in strongest spirit, rum does all very well as a killing agent, but something stronger is needful for preserving animal tissues in a fit condition for examination. Your correspondent speaks of 'diseased' leaves: in what way are these leaves diseased? What is the nature of the injuries inflicted on the tea-bushes by this supposed pest?"

RICHARD BLECHYNDEN, Junior.
Deputy Secretary.

May we suggest that the sub-committee now investigating the cacao disease, in conjunction with Dr. Trimen, do make it part of their duty to form a thoroughly representative collection of all the presently known enemies of the tea and cacao trees in Ceylon, to be eventually deposited for public benefit in the Colombo Museum. They could then at all events point to some tangible results of their labours.

We have received from a correspondent a box containing a part of a tea-stem with a borer at work inside; and he accompanies it with a letter, which says:—

Dear Sir,—I forward under separate cover a piece of a stem of a dying tea bush with the borer attacking it enclosed. The borer had made an entrance about a foot above the ground and had bored his way for about 18 inches up the stem. At the point of entrance the tree was completely hollowed out, the bark only remaining. The stem when I found it had been blown over and had almost the appearance of being cut by a saw. If you can identify the borer, I shall be glad to know what it is.—Yours faithfully, B.

We sent the box on to our referee, who replies:—"The borer is the red one, *Zeuzera Coffeæ*, described in Nietner's book, No. 13, p. 14." This is the brute that has been known, somewhat rarely happily, to attack cinchona, and we hope his liking for tea will not show any more striking signs than at present: if not we shall do well. His bump of destructiveness is very feebly developed compared to that of the terrible borer of the Bambu districts of the Wynaad.

VANILLA.

As much as 36,539 pounds of vanilla have been imported to this country in a single year, and there is scarcely any odor or flavour with which we are more familiar. Perhaps the pungent peppermint might claim precedence, but even this is doubtful, since the odor of the fragrant bean rises from a large proportion of those popular articles of consumption which are furnished by cooks, confectioners and tobacco-dealers.

The vanilla plant is indigenous to the hot and moist woods of eastern Mexico, and is cultivated by fastening shoots to trees just near the ground. The shoots soon strike root, begin to produce fruit in about three years and bear for about thirty years. From Mexico the plant has been transported to the West Indies, several of the East Indian islands, Bourbon and Madagascar. It is a long, dark, shining bean, and shaped like that of the Catalpa tree, which we still see in our streets, only the vanilla bean is not smooth, but corrugated. The name vanilla is derived from the Spanish word *vaynilla*, the diminutive of *vayna*, a pod.

When the green color of the fruit begins to change, and before it has become ripe, the beans or pods are gathered and prepared for the market. Sometimes they are steeped in hot water or partly sun-dried, and then wrapped up in blankets until moisture exudes, when the process is repeated. This is supposed to cause fermentation in some portions of the fruit and develop the aroma. After treatment the pods are packed into bundles of fifty, the bundles being sometimes enveloped in tin foil, and they are then ready for exportation. Workmen who handle vanilla are exposed to certain accidents which arise from its dust and emanations. They suffer from soreness of the eyes, and the arms and face swell and become the seat of annoying eruptions. They are also liable to headache dizziness, nervousness and pallor.

When the Spanish conquerors came to Mexico they found that vanilla was in common use by the natives for flavoring chocolate, and this alliance has met the approval of all succeeding years. One suggests the other as ice cream also suggests the odorous bean. Although there are the Bourbon, Costa Rican and Venezuelan vanillas, as well as those of Brazil, Peru and Spain, the Mexican vanilla still ranks as the best. The Venezuelan has a flavor of the tonka bean. The odor of the tonka bean just referred to, as well as that of the melilotus, or sweet clover, resembles vanilla somewhat, and is owing to the presence of a certain substance called coumarin which these plants contain. This substance will produce poisonous effects, and thirty to sixty grains have caused nausea, depression and drowsiness. The poisonous results which have at times followed the use of vanilla ices have been said to be owing to the presence of cardol, or the oil of the cashew nut, since that is occasionally used to improve the appearance of vanilla. These cases are distinct from those in which the poisoning has been caused by the admixture of dangerous metallic substances.

A plant the flavor of which is connected with so many of the simple enjoyments of life, as well as the grandest festivities, may justly call for a passing notice from those who "mind the why and wherefor."—(*American*) *Hour.*

CONSUMPTION OF COFFEE IN VICTORIA.—The *Australasian Trade Review* gives the following statement:—

"Coffee. (Duty, 3d per lb)

		1881.	1882	1883.
Imports...	lb.	1,535,413	1,236,833	1,289,666
Exports	,,	620,170	494,408	418,408
Transhipments	,,	140,232	59,464	61,656
Home consumption (less drawbacks)	,,	863,768	868,225	947,424

"The figures given above show a satisfactory increase in the home consumption of coffee in 1883, an increase represented by 79,199 lb., as compared with 1882. The re-export and transhipment trades, however, have fallen away to a large extent. Imports have been on a steady scale, and in fact, taking the aggregate of the three years, have not quite come up to requirements. Stocks, therefore, have been gradually reduced during the period named, but this can only be regarded as a sign of health."

The consumption of coffee, the article being *very largely* mixed with chicory, as a rule, is in Victoria as nearly as possible 1 lb. per head against over 7 lb. of tea.

COCOA AND CHOCOLATE IN VICTORIA.—There seems to be a moderate demand for cocoa in Victoria, the beans being free of duty, while tea and coffee are liable to 3d per lb. on import. The following is from the *Australasian Trade Review*:—

"(Duty, 3d per lb; Cocoa beans, Duty free.)

		1881.	1882.	1883.
Imports...	lb.	302,050	348,060	315,537
Exports...	,,	59,999	51,218	48,283
Transhipments	,,	32,061	10,812	848
Home consumption (less drawbacks)	,,	274,476	307,174	278,424
(The above figures do not include chocolate confectionery).				
Cocoa Beans—Imports...	cwt.	789	807	1,226

"At first sight, the figures stated above do not quite bear out the opinion we have formerly expressed as regards the expansion of the trade in cocoa and chocolate. But we had in mind all the forms in which the latter article is presented to the public, inclusive of those which come under the denomination of confectionery. As a statement of the whole of the trade, therefore, the Customs satistics are not complete. It will be noticed that the importation of cocoa beans, which come in duty free, has increased very largely, pointing to growth in the local manufacture."

THE SEASON IN TRAVANCORE.

A correspondent writes from South Travancore: "I was rather surprized to see a para in your paper stating that the rainfall on the west coast is almost equal to the average of last year. If this refers to Malabar and South Canara, of course people in Travancore will have no cause for complaint. But in Travancore, from the district in which I write, we had 25 inches of rain up to the end of June last year; in the corresponding period this year we have had 5 inches of rain! Near hilly places there may have been an inch more, but on the sea coast it has been considerably less. We have not had a single monsoon shower. The paddy crop of Nunganad has been reared by the water from the hill streams. As for fodder for cattle, there is none. Rice is coming in from the east in carts and quotations have gone up—the present price is five Madras measures for the rupee, a rate sufficiently high to induce the authorities to look at matters more seriously than they are doing at the present time. It is the opinion of many that the unfavorable condition of the season in Travancore has created such a demand for grain in the British stations near by that scarcity threatens and grain will soon be dearer there than here. It is certainly time that the British Government advised the Travancore authorities to delay no longer in accepting the project for laying down of the railway from Tinnevelly to Travancore. It is in the interests of both the British and Travancore Governments that this should be done. It is the impression here that owing to influences brought to bear upon the Maharajah's Government, the Tinnevelly railway will not be undertaken, but the other and dearer route. It would be a fatal mistake if the Travancore Government accepts the advice of interested parties, and puts off indefinitely the carrying out of a work that will be of the greatest advantage to the people. The Tinnevelly route will pay; it will bring Travancore in direct railway communication with the grain producing tracts in Southern India; it will be the cheaper of the two routes and there will be less engineering difficulties in the way. Instead of the Dewan and the Maharajah giving attention to this important matter, they have reorganized departments, ordered commissions to sit, raised taxation, raised the salaries of the better paid officers, while the poorly paid, those on the receipt of a few *chukrams* a month, are allowed to put the screw on as tightly as they can on the poor ryots and thus eke out their existence. This is following the old saying,—To him that hath shall be given. Reform in spite of all that people may say of Travancore, is wanted, and the sooner it is carried out in the right direction the better for all concerned."—*Madras Standard.*

THE DEPRESSION IN THE PRODUCE MARKETS.

The following interesting article, slightly abridged from the *Statist* of June 7th, does not touch on Mr. Goschen's theory that the current low prices for produce are largely due to the present relative scarcity of gold. He argues that after the great increase in the yield of gold caused by the discoveries in California and Australia, prices throughout the world rose for a series of years. The yield in those places has now become small, and indeed the strange circumstance of an export of gold to Australia was recently generally noticed. Gold is at the same time in more demand owing to several leading countries having adopted a gold standard. Mr. Goschen thinks that if the relative abundance of gold, a generation ago, caused prices to rise, a relative scarcity now makes them fall. In other words when sovereigns are very plentiful they buy less, because other commodities become dearer; when sovereigns become scarce they buy more, because commodities become cheaper. To some of those connected with Eastern trade, it appears likely that the effect, if any, of the so-called "appreciation" of gold in depressing prices, is helped by the simultaneous "depreciation" or fall in the value of silver. That precious metal is produced in increasingly great quantities, and owing to its demonetization in several European States, it is poured into the Eastern world, where a gold standard is unknown. The first effect of the influx of silver in India, China, &c., was similar to the effect of the gold discoveries in Australia and California. Prices rose, and as they did so more rapidly than wages, production was enormously stimulated and exports increased. The larger supplies were poured into Europe, when the intricate operations of the exchanges and the interplay of the greater scarcity of gold here, and of the greater abundance of silver in the East, were unconsciously set to work to equalise matters. The temporary effect may be to supply Europe with more Eastern produce than is required, and if so, part of our plethora of stocks may be due to this cause, which, however, can only be a temporary one, to be set gradually right by a rise in wages in India and the East, and a fall in the exchanges to the point that may discourage production. The questions of the effect upon prices, of the appreciation of gold and the depreciation of silver, are far too weighty to be dealt with in a few sentences, and it may indeed be doubted whether any mortal mind be subtle enough to solve them. The questions are only named here as an introduction to the article in the *Statist*, where improved communications are laid most stress upon as a cause for the existing depression:—

(Abridged from the *Statist.*)

"The financial stability, we might almost say stolidity, of English commerce could have few better proofs than the, to outward seeming, easy way in which the extreme depression in the produce markets, technically so called, has been borne. The *cœur leger*, none the less, has had to bear up against many a sorely-taxed banking account; little reading between the lines is required to tell us that, while the strain has come heavily upon those best able to bear it, the grand old days of the Anthony Hamblins have gone, never to return. Many things have happened since John Company died, a quarter of a century ago, but none more strange than the complete revolution that has overturned all old business traditions and customs.

"Anyone can see at a glance that the prices of produce are woefully depressed; but it is not so readily recognized that the depression is permanent, and that all business is transacted upon a lower plane. It could be easily shown that this shifting of the level is universal, that the whole commercial stratification has been displaced by an irretrievable cataclysm; but it will be convenient to restrict ourselves to produce proper, which may be roughly defined as either the natural produce of the soil, or such produce as is cultivated or extracted with a minimum of labour. That the market quotations of such articles will ever permanently rise to their former level, we cannot predict, even if we would. Whatever the inconvenience to individual firms or corporations—and no great change can avoid causing such—a state of things which cheapens almost every article of necessity and even luxury cannot honestly be deplored. Cheap food in a manufacturing country such as ours implies the capacity for putting up with lower wages, and consequently confers increased strength to endure the competition with other nations. And though some suffer, others are acute enough to discern and agile enough to accommodate themselves to the altered conditions. Wealth is not diminished in amount by more impartial distribution, and such spreading of the waters is fertilizing and in every way beneficial.

"The serious lowering of values is concurrent with an enormous increase in production, and in the resulting stocks held in the main depots. These results are universal; the examination of a few typical cases will help us to discover the common cause. Sugar is a valuable instance in point. It has the peculiarity of being produced from two vegetable growths totally different in their character, peculiarities, and mode of cultivation. It is consequently to a greater extent even than such an article as coffee—which, though widely distributed, is confined to tropical climates—independant of failures of crop in any one region of the globe, while its universal consumption raises it beyond the influence of the caprices of fashion or taste. Prices have become lower and lower, until a point has been reached whereat some assert it were better to throw the land out of cultivation. We do not agree in the opinion, but undoubtedly profits must be of the scantiest. The stocks of sugar in this country alone run fully 100,000 tons above those kept four or five years ago. The total imports last year exceeded a million tons, and while the consumption per head of the population also, as was natural, rose above the stationary point of recent years, it is incontestable that consumption cannot keep place with production.

"Tea is more liable to be affected by good or bad

seasons, but even here the opening-up of new fields becomes daily more apparent as a re-agent. While the consumption per head in this country has remained remarkably steady for some years, the proportion of Indian has increased from 19 per cent of the total in 1878 to 33 per cent in 1883. Disregarding extreme and temporary fluctuations, we find the value of common Congou ranged until 1880 between 7d and 9d per lb. Since that time the variations have been between 4d and 6d. Parallel to this, the stocks, which fluctuated between a yearly minimum and maximum of 50 million and 110 million pounds respectively, have during the latter period found the annual limits increased to 80 millions and 130 millions.

"Tea is essentially a British drink, but coffee, on the other hand, is not, indeed its consumption is diminishing year by year. The 14,000 to 15,000 tons consumed in this country, even with a stock equal to eighteen months' consumption would not account for the very heavy fall in prices of all descriptions. Quotations are, indeed, better at present than the abnormal figures of last year; but it will be remembered that these were a reaction from the speculation induced by shortages, of rumoured shortages, in the Brazilian crops. It is more to our purpose to note that while the total crops of Java, Ceylon, and Brazil amounted in 1871 to 289,000 tons, those of 1883 totalled 476,000 tons. The *minima* of stocks have during the last three years far exceeded the *maxima* of years preceding. The highest point reached in 1877 by the stocks in Europe, Great Britain, and the United States was 131,900 tons; in 1883 the enormous total of 244,400 tons was attained.

"Rice is another marked example. This it is in spite of being subject to causes of fluctuation which do not affect some other staples. Its area of production is comparatively restricted consequently it is more affected by climatic influences, and also is more easily held in hand and manipulated by speculators. It is also, to a certain extent, dependent upon the corn harvest, being an available substitute for grain in the manufacture of raw spirit. The price per cwt has slowly dropped from 15 to 20 per cent below the range of a few years back. The imports into Great Britain and Europe rose from 618,000 tons in 1879 to 850,000 tons in 1881, falling to 707,000 tons in 1883. Despite this, the stocks, which had been 276,000 tons in 1881, stood at 153,000 tons in December, in 1883, as against 110,000 tons four years previously.

"When we say that we are not aware of a single article of produce that cannot be arraigned in like terms, and when, moreover, we assert our conviction that this transformation is absolutely permanent, it will naturally be supposed that the cause is neither superficial nor temporary. Nor is it. Is it a truism, too frequently put on one side simply because it is a truism, that the advances of modern civilization, the infinite ramifications of steam and electricity, have entirely altered all the old modes of doing business. Now that we are beginning really to feel the pinch of these alterations, we come to realize what they really are. Steam and electricity have increased production, facilitated distribution, and equalized prices.

"The increase of production is the most patent result. By railways and steamships and steam machinery, new countries of vast extent have been opened up. The most savage of nations are quick to perceive the small amount of labour by means of which they can procure the invaluable treasures of Manchester prints and Birmingham jewellery. Settlers find that a competency, if not wealth, can be easily earned by less exertion than in a civilized country would barely suffice to keep them out of the workhouse. Even old countries—in the rural districts of which the peasants are woefully ignorant—are opened up and made doubly reproductive. The dwellers in the great Central European plain have probably less claim to genius than the tribes of the Mongolian plateaus but they have been shrewd enough to build up the magnificent industries of beet sugar and potato spirit. Further, modern invention has greatly simplified the methods of preparing and packing most staples. This not only tends to greater economy, but diverts the economy whither it is most highly appreciated. The labourer can get a proportionately higher price for doing less work when the chemical, laboratory and the hydraulic press are put up at his doors by the capitalist. Any loss on over-production does not fall on the actual producer, whose wage is already at a minimum, who is glad if he can sell his wares at all, regardless if the purchaser can sell them at any price.

"But these modern agencies do as much in facilitating distribution. The development of the mercantile marine cheapens the cost of carriage, and combined with telegraphic orders multiplies to an enormous extent the points of delivery. It would appear at first sight that this increased ease of purchase would lead to an enlarged demand, and so to some extent it does. But it is equally apparent that it ends in a greater degree to depress prices by enabling buyers to be independent of one market, and thus getting up a strong, often suicidal, competition between markets. If a purchaser can, as far as convenience is concerned, buy indifferently at Hamburg, Havre, or London, trades-unions or 'rings' to support quotations become a cruel impossibility. Another direct effect is the doing away with middlemen and their profits. A more dangerous result is the multiplication of traders, especially of traders with little or no capital. The information—if we could get it openly—of the bill brokers would inform us how large is the nominal business done by firms of yesterday, and heavy the losses borne by historic old houses in their vain attempts to keep pace with these mushroom growths.

"The third effect is the equalization of prices. In common parlance, everybody knows everybody's business. The days of trade secrets and *grands coups* on special information are gone. No Rothschild will ever again make a fortune over a battle of Waterloo. Any important incident is immediately and simultaneously announced on the exchanges of both hemispheres; stocks afloat and ashore are known and watched from hour to hour; imports and consumption are gauged to a nicety. There is no one mart, no one market which rules the world's trade. The prices at New York, Rangoon, or Sydney are turned into London prices by the mere mechanical application to a set of tables. If the sun did not present one insuperable difficulty, all the exchanges of the world would open and close at the same hours. As it is, prices follow each other round the globe from east to west. This changed order of things has rescued all and every branch of trade from the grasp of any possible monopoly or combination."—*Produce Market's Review.*

SANGUINE VIEWS OF RICE CULTIVATION IN CEYLON

are given by a correspondent of the "Times of Ceylon" who signs himself "Taprobane." If the natives, however, are so lazy and unenterprizing as he represents them, we fail to see how the additional 100,000 acres are to be cultivated :—

Given a proper supply of coral lime to the soil, cheap transit for manure, proper cultivation, a regular but moderate supply of water with proper application of the same, and I will undertake to say that rice cultivation in Ceylon might not only be carried on with the greatest vigour, but be made to yield a return equal to that obtained in value from the cultivation of so-called European products, and I think it would be for the interests of the Government, the Planters' Association, and the Ceylon Agricultural Association to encourage the Sinhalese cultivator to stick to his paddy instead of tempting him to forsake, as he would, his legitimate industry for other products, the manufacture of which requires science and skill, and which the native villager knows nothing about nor would ever be likely to acquire, but would most probably injure the general reputation of the products of those who are best able to support their fame. I say so from no selfish motive whatever, for I have nothing to do with European products.

It was also urged that "it might be inferred that the Government of Ceylon ought specially to aim at making Ceylon independent of India in respect of the rice supply of its urban and immigrant population," and that "Great Britain might as well hope to become independent of foreign grain." I say that this is simple

nonsense, for if it can be shewn, by the means I have just stated, that Ceylon is quite capable of raising as much rice as would supply its urban and immigrant population independent of India I consider it is just what the Government of Ceylon ought to aim at, and not only that, but to use every possible means in its power to obtain such an important and desirable object.

To make Ceylon independent of rice from India we should have to raise yearly about 14 million bushels of paddy more than we do at present in order to obtain 7 million bushels of clean rice, two bushels of paddy giving one bushel of rice. Let us say that the 600,000 acres at present under paddy culture, without any artificial appliances whatever—not even so much as is to be found in India—without any scientific cultivation of the soil, no lime, no manure—except what is derived from the mineral ingredients conveyed by the water in a state of solution, or found in the sediment deposited by the water on the soil, and probably a little *ammonia* from the rainfall—affords sufficient food for the three million souls which comprize the population of the island, *minus* seven million bushels of rice which we yearly import from India; and, supposing that these 600,000 acres are already so much exhausted that, even with all the above-mentioned applications, the soil could not be made to yield from one-half to as much again of the present yearly produce, which I am confident it could; without, therefore taking this increased yield into consideration at all, I do not hesitate to affirm that 100,000 acres of additional land, under suitable circumstances of soil, climate, and a regular but moderate supply of water, with a modern system of cultivation, would make Ceylon totally independent of India, and save us two millions sterling yearly; perhaps more when, by-and-bye, more immigrant labour will be required in the island.

A CUP OF TEA.

"What should we do without tea?" is a question often asked by the fair sex, and I think in many cases it is echoed by members of the sterner sex, though they do not care to own it. Much has been said for and against "the cup that cheers, but not inebriates," and I suppose such will be the case while it exists as a beverage. Of course an excessive use of tea is ruinous in its effects on the nerves, but then these bad effects are generally preventible. Very few people know how to make tea wholesomely. Notwithstanding its almost universal use, the greatest ignorance prevails with regard to infusing tea so as to render it a wholesome beverage. The use of tea medicinally has been known for generations, and anyone studying the subject will find that while we may make it one of our best friends, we may also turn it into one of our bitterest enemies. In favor of tea it may be said that it is a restorative and sedative, while it allays vascular excitement and at times even eases pain. It is good in cases of fever, with restlessness and debility, in nervous headache, in neuralgia, in gout or rheumatism, and in colds or coughs. But to do good tea must be scientifically infused, and not used too often. Properly once a day is enough, but at most it should only be taken twice. Nothing is more deleterious than the practice indulged in by so many women of sedentary habits of drinking tea on all possible occasions. Indeed, instances have been given of dressmakers who made it a custom to take seven or eight cups of tea a day, and the consequences may be easily imagined of such a pernicious custom. The digestion is destroyed, the nerves are unstrung, and other ills follow in due course. In making tea the following rules should be observed, when no bad effects will arise from the use of it:—1. Never make tea with water that has been boiling for a long time, as it is decidedly flat. 2. Never make it unless the water is quite at boiling point; the lid of the kettle should be rattling. 3. Be sure and heat the teapot thoroughly, and it is a good plan to hold the teapot over the fire for a moment after putting in the tea, and before putting in the water. 4. Never infuse tea longer than eight or ten minutes; if it has to wait, pour it off the leaves into another teapot. 5. Never stew tea by the side of the fire. By attending carefully to these rules all the pernicious effects of tea are avoided; and in conclusion I would give a word of advice to mothers, and warn them not to give tea to young children, as nothing can be worse for them.—*Leader.*

COCA IN PERU.

The following is part of a pamphlet published by Mariani, Chemist, 41 Boulevard Hausmann, Paris:—

(*Translated for the "Ceylon Observer."*)

Its Botany.

The *Erythroxylon coca* (Lamarck) of the family of Linaceæ inhabits the same equatorial regions as the cinchona. It is a shrub from six to nine feet high and is cultivated in South America, principally in Peru and Bolivia, Equador, New Granada and Brazil. The trunk is covered with a rough bark, nearly always glossy. The branches often drawn together towards the summit bear alternate leaves, somewhat variable as to size, elliptic, of a darker green on the upper than on the lower surface. The distinctive characteristic of the leaf is the arrangement of its veins: parallel to the middle vein are two longitudinal projections, which starting from the base of the leaves extend to the point, describing a slight curve. Its ramous root with oblique divisions ends in fine branches. The small white or greenish yellow flowers are either solitary or grouped in small clusters at the hollows by the scaly bracts. The fruit is a pod enclosing seeds which are usually surrounded by abundant albumen.

Cultivation.

A light, siliceous soil, a mean temperature of 15 to 18° centigrade, a certain amount of moisture—these are the essentials for the perfect development of the coca. According to Papig, in the valley of Chincao and of Casapit, the land in which the coca flourishes offers rather a rapid slope, but the soil is very fertile, it being a red brick-clay, containing probably iron. The seeds of the coca are sown in layers known as "Almarigos." The young plants are protected from the sun by plaited branches or mats and then transported into furrows 18 centimetres wide and 7 centimetres deep and one foot apart. The space between is planted with maize, the shade of which protects the young plants. Under the kindly influence of sun and rain, the growth of the shrub is rapid; it flowers in from four to six months, and soon gives the fruit. It attains its full size (average 2½ yards) only in about five years. Efforts have been made to acclimatize the coca plant in Europe, but hitherto without success. Frail specimens are found in the Botanic Gardens in hot-houses in Paris and in London, and with some of the great Belgian horticulturists. Corsica and Algeria would seem to offer the climatic conditions necessary to its successful growth, and we are about to endeavour to grow the plant in these two countries.

Harvesting.

The coca begins to yield its first harvest in about a year-and-a-half. The gathering should be performed in dry weather. It is generally entrusted to women, and consists simply in separating each leaf with the fingers,

The leaves are received in wrappers or rugs and carried with care to sheds protected from rain or damp where they are dried and packed.

In 1851, the annual produce of Bolivia was reckoned at more than 400,000 *certos* (4,600,000 kilogr.) three-fourths of which came from the province of Yungas.

From Paul Marcoy's Travels in the region of Titicaca, we borrow the following passage:—"Of all the valleys in the group of Carabaya, Ituata is the one in which coca is cultivated on the largest scale. They were then in full harvest, men and women at work in the quincunxed plantations of this shrub which is so dear to the native race that a decree of 1825 placed it in the shield of the Peruvian arms opposite the Peruvian sheep and the horn of plenty. Men and women one by one were carrying bundles in which were wrapped the leaves they had gathered. These leaves spread out on large linen covers were exposed to the sun for two or three days, then heaped in sacks one yard square and dispatched to all parts of the territory. The coca harvest is a time of rejoicing for the natives of the valleys just as our wheat harvests or vintages are in Europe. On the last day of ingathering, the two sexes who have shared the labour meet and with dancing and libations show the joy they feel at having no more work to do."

HISTORY.

Glance over the histories of the conquest of India of Oviedo, Pedro Cieça de Leon, Zarate, Lopez de Gomara and others, and you will have some idea of the astonishment and wonder which the sight of the "coca" produced in their minds. These men, arrived in an unknown world, are dazzled by the sight of the profusion of gold in the palaces, in temples, and even in simple dwellings; their eyes sparkle with envy at the sight of so much wealth, which they have come so far to seek and for the conquest of which they are about to commit atrocities unworthy not only of the name of Christian but even of barbarians.

What is their astonishment to see that this gold, for which they show such eager desire, is almost disdained by the Indians, who seem to attach more value to a miserable little dried leaf. What then, are the marvellous properties of this leaf, which is used for money, but the use of which is forbidden to the common people, it being reserved for sovereigns and priests, which is in some measure a sacred seed, since it figures in sacrifices, is found in temples and in statues of divinities? At first they are tempted to regard it as a gross superstition, but facts soon come to enlighten them and to convince them that the Indians are not wrong in attaching so high a value to this apparently insignificant leaf.

These natives whom they have conquered and of whom they have made slaves—not only do their conquerors despoil them of their wealth and torture them to extract more gold, but they make use of them as beasts of burden, giving them heavy loads to carry over difficult mountains and obliging them to run before their horses. Well, these unfortunate Indians stand fatigue which ought to kill them: they make long marches, carry missives, running day and night, deprived of all food, not even finding water on those arid rocks. How can they sustain these almost superhuman labours, and be always gay, lively and ready, not seeming to give in for a moment? They have in the mouth a pinch of coca leaves which they chew and that suffices to sustain them, to refresh, to rest them and to give them fresh strength. The Indians call the coca plant divine and attribute to it the most marvellous properties.

In Peru, under the empire of the Incas, the coca was regarded as a living representation of divinity, and the fields in which it grew were venerated as sanctuaries. The Indians made a talisman of it; through it were obtained the favours of fortune, the triumphs of love, and the cure or alleviation of disease. The coca made the oracles speak and rendered their replies less terrible; it preserved the hearth from all accident or crime. The Indian could not visit the tomb of his ancestors or call up their spirits without a little coca in his mouth. But all were not worthy of making use of this precious plant; for a long time it was reserved for the use of the gods and of the Incas, those grand monarchs who were said to be descended from the gods. None might chew the coca but those whose virtues or high deeds had made them worthy to share it with the sovereigns; it was the reward of bravery or of any heroic action, and was preferred far before gold or silver.

Through contact with Europeans, the Indians gradually dropped their superstitions, and, after the conquest of Peru by the Spaniards, coca came into general use and it became an important article of commerce, without however losing its marvellous prestige. According to the natives it was coca which gave them patience and strength to endure the severe labours which their new masters imposed upon them. But, like quinine, this plant was to have its enemies: people attacked its usefulness, pretended that the belief of the Indians, who imagined that they found strength in chewing the leaves, was a pure invention of the devil, and the use of it was forbidden as irreligious by the Second Council of Lima.

Since then, the authority of a great number of learned men has pleaded for the divine plant, and experience has shown that the Indians of the mountains, who of all the natives are those who make most use of the coca, are those who stand the hardest work, and labourers throughout South America have continued to use the coca. The Indian goes to no work, undertakes no journey unless his *chuspa* be full of beans, and three or four times a day, he sits down, takes some leaves out, puts them one by one in his mouth with the addition of a little *llipta* (lime), chews them, and then goes on his way, still sucking the juice of the beneficient plant.

We must not regard the legends attaching to the history of the *coca* as so fabulous as many have thought them. Separated from the superstition that surrounds them, they still go to prove the divine virtues of the plant. Thus, the Indians could not visit the tombs of their ancestors without chewing it; in point of fact, the exhalations from the tombs are unhealthy and poisonous unless counteracted by the tonic properties of the coca.

Minerals could not be drawn from the mountain unless the miners were chewing the sacred leaf, the fact being that the juice of the coca gave the miner strength to strike vigorously enough to extract the metals. If we take up one by one the fables that the Peruvian has piled up concerning this marvellous plant, we shall see that they really only exaggerate a truth. It is certain that the Indian, without substantial nourishment, does very heavy work, and it is coca that supplies the place of what is wanting in his food. The Spaniards, noticing this remarkable fact, recorded it in their reports which were eagerly read in Europe From that time forward, coca has found a place, not only in all the stories of the New World, but also in all the works on natural history, medicine or pharmacy.

NICHOLAS MONARDES, a doctor in Seville in the 16th century, was the first to make known coca in a book, the first edition of which appeared at Seville in 1565. "L'Histoire Générale des Plantes," published at Lyons in 1653, vol. 2, p. 745 gives the French translation of what Monardes said upon coca.

JOSEPH AGOSTA, in his "Natural History of the Indians, Eastern and Western," says in his summing up, upon coca:—"For my part, to tell the truth, I am convinced that it is not simple imagination, but a fact that

it gives strength and courage to the Indians ; for one sees the effects of it in enabling them to march for several days upon nothing but a handful of beans."

LINNÆUS, the celebrated naturalist, says that coca possesses "the penetrating aroma of vegetable stimulants, the binding and strengthening virtue of astringents, the antispasmodic qualities of bitters and the nutritious mucilage or gum of analeptics or the food-plants." "This leaf," he adds, "powerfully exerts its activity on every part of the animal economy : *Olido in nervos, sapido in fibras, utroque in fluido.*"

The doctor UNANUE, of Lima, regards it as *the* tonic *par excellence* (architonico). He recommends it for "*nervoses stomacales*" and for convalescents, as conducive to quick recovery after exhausting diseases.

Father DON ANTONIO JULIO wrote :—"This plant is a preservative against many sicknesses, restores lost strength, and is a lengthener of human life. It is a pity that so many poor families are without this preservative from hunger and thirst ; that so many employees and labourers have to do without this valuable support ; that so many young and old men, devoted to the ungrateful task of study or of writing should not enjoy the benefits derivable from this plant, which lessens the exhaustion of the vital powers, the debility of brain, and the feebleness of digestion which are the inevitable results of continuous study."

WEDDELL considers coca as an excitant the slow and sustained action of which differs from that of alcohol.

According to BOERHAAVE "the saliva charged with all the bitter and mucilaginous particles of coca brings to the stomach, besides vital invigoration, real nourishment which, digested and converted into a nutritive and abundant chyle, is introduced into the circulating current and is changed in to the human substance according to fixed laws."

MANUEL FUENTES of Lima, from whom we borrow the above quotation, adds :—"However it may be with these explanations, the real fact is that the human body by sustained use of coca acquires an athletic constitution capable of standing the hardest work in the midst of privations and of misery and in inclement weather."

The light which experience and analysis give, reveal in coca the most tonic plant in the vegetable kingdom. This most precious shrub combines in itself alone the different virtues which are found in the large number of vegetables comprized under the head of *tonic* plants."

LITTRE and CH. BONIN (*Dictionnaire de Médecine, de Chirurgie et de Pharmacie*):—"Coca leaves four centimetres long and 27 millimetres wide, are the object of a considerable trade. Masticated in small quantities by runners, travellers and miners, they enable one to pass one or two days without taking solid or liquid food ; they allay hunger and thirst and sustain the strength. Masticated in larger quantities, they act like wine; mixed with tobacco and chewed, they have an effect similar to that of *hashish*."

Doctor SCHWALK gives an observation on pneumonia very distinctly marked which was cured by some infusion of coca :—"The experiments which I myself have since made have been crowned with success, whether in several cases of sharp primitive pneumonia or in others of consecutive pneumonia. Coca deserves, according to my opinion, the praises which the historians of Peru have for centuries bestowed upon it. This wonderful plant appeases hunger and thirst and diminishes one's need of sleep. It is in a word a powerful restorative of the vital forces, and is called to play an important part in the cure of the digestive and respiratory organs."

Doctor CH. GAZEAU (Thèse pour le Doctorat, Paris, 1870) :—"We have thus summed up the physiological, action of coca : upon the stomach, gentle excitement, anæsthesia and probable increased secretion of the gastric juice ; upon the intestines, increase of the intestinal secretions, &c. These multiple physiological activities upon the digestive tube may be summed up in a specific action in the numerous functional disturbances, so various and so little understood of the vital organs."

The same author quotes a large number of observations on this subject in which coca has never failed to cause "an admirable, often even a marvellous action," and he concludes :—"It seems to me useless to quote other facts ; these suffice to authorize the wide generalization, coca is *the special* medicine for diseases of the digestive tube."

Professor O. REVEIL finished his article on coca by saying :—"There is still much to be done in the clinical and physiological study of coca. We know that it acts on the muscular, nervous and sensitive system. This substance is destined some day to occupy an important rank in therapeutics."

The physiological action of coca has been well described by Prof. See, who ranks it with the disassimilants.

Dr. CH. FAUVEL prescribes it daily with much success in his *Clinique de Laryngoscopie* under the form of "*Vin Tonique à la Coca de Mariani*," and prefers it to quinine in many diseases, principally in affections of the respiratory passages and the vocal organ.

We one day asked Dr. Fauvel what made him think of using coca for diseases of the throats when no one else in France had thought of this use. "It is quite a little history in itself," replied the doctor. "Fully twenty years ago, I had an old friend, then vicar of Bondy, the learned abbe Pullez, who was always talking to me of the marvellous effects of coca in cases of weakness of voice, and affirmed, that, whenever he had to preach a long sermon, he took coca for two days and thus obtained a sonorous and considerable volume of voice. After these persistent affirmations, Dr. Fauvel ventured on trying coca with patients afflicted with feeble voice and was soon conviuced that his excellent friend had made him discover a medicine which can justly be called the tightener of the vocal cords.

Professor GUBLER (*Commentaire Thérapeutique du Codex*, art. *Coca*) thinks that, like tea, caffeine and theobromine, coca gives to the nervous system the strength with which it is charged, acting as a battery, with this difference that it gives it up slowly and not all of a sudden.

A. DICKEMBRE says (*Dictionnaire Encyclopédique des Sciences Médicales*, art. *Coca*) :—"The theory of the batteries imagined by M. Gubler agrees so exactly with the phenomena observed that Mantegazza, without generalizing or pretending to make any theory, said, confining himself to descriptions of what he had seen : 'Under the influence of coca, it seems that a new strength is gradually introduced into our organism, as water into a sponge.'"

EXTRACTS OF COCA.

In 1774, Dr. Unanué (of Lima) first studied the constituent principles of the coca leaf. He treated 250 grams of fresh coca leaves with boiling water, and obtained 71 gr. 60 cent. of a gummy dark green extract of a pleasant odour reminding one of the smell of the leaf, and of a bitter taste which left on the tongue a sharp and durable impression.

We wished to verify the experiments of Dr. Unanué, and, although we had to operate on dry leaves, the same quantity of coca (250 gr.) gave us 76 gr. 25 cent. of gummy extracts, that is to say 4 gr. 65 cent. more than in the experiment of the Lima doctor.

Treated with boiling water by alcohol at 21°, 56° and 95° and finally by ether, the coca leaf reduced to

powder gave us the following quantities of extracts :—

1 Kilogr.	of coca,	exhausted by boiling water,	gave 305 grammes of extract.
1	do.	do.	Alcohol at 21 deg. gave 365 grammes of extract.
1	do.	do.	Alcohol at 56 deg. gave 356 grammes of extract.
1	do.	do.	Alcohol at 95 deg. gave 210 grammes of extract.
1	do.	do.	Sulphuric ether gave 196 grammes of extract.

The extract obtained from boiling-water contains only gummy mucilage.

The extract obtained from alcohol at 95°, as well as that obtained by sulphuric ether, contains the azotized fatty principles, resin, chlorophyle, tannin and the alkaloid of the leaf.

The extract obtained by alcohol at 21° and at 56° contains all the gummy and resinous principles of the coca leaf, as well as the fatty azotized principles, tannin, the alkaloid and chlorophyle. It is this extract which best represents the exact proportions of the constituent principles of coca. The wine of coca at 21° and the elixir at 33° are therefore the most powerful preparations.

ALKALOIDS OF COCA.

COCAINE ($C_{32}H_{40}Az_2O_8$).—In 1850 M. Niemann drew from the leaves of coca a new alkaloid, to which he gave the name of *cocaine*, the formula of which we have just given.

A kilogramme of coca leaves gives about two grammes of cocaine. This alkaloid is very bitter and produces a marked numbness in the tongue when placed in contact with that organ. It is of a yellowish white and appears under the form of silky prisms. It is almost insoluble in water, pretty soluble in alcoholized water, very soluble in alcohol and in ether.

Cocaine has a strongly alkaline smell; it neutralizes acids completely and forms with them, salts entirely crystallizable.

ECGONINE.—Cocaine heated to 100 degrees in a sealed tube with concentrated hydrochloric acid divides itself into benzoic acid and a new base for which M. Wœhler has proposed the name of *ecgonine*, derived from the Greek. Ecgonine crystalizes in rhomboidal oblique prisms, without smell, sparkling and enclosing a molecule of crystallized water. Very soluble in water, this ecgonine is but slightly soluble in pure alcohol and quite insoluble in ether.

HYGRINE.—Hygrine, from the Greek *hugros* wet, is a liquid alkaloid which M. Wœhler discovered while treating coca leaves with amylic alcohol. The smell of it reminds one of trymethlamine; it has a strong alkaline re-action, and the taste of it is not bitter; its hydro-chlorate is crystallizable, but it is deliquescent. With the bichloride of platinum it forms a flaky precipitate.

At the end of the pamphlet are given the various preparations of the leaf which the author offers to the public, such as, Pâte (paste) Mariani tonique and pectoral; syrop de coca; infusions; alcoholic tincture; pills; hydro-alcoholic tincture or extract for the immediate preparation of coca wine; and lastly powder.

THE amount of sugar produced in the Burdekin district during this year is expected to be about 7,500 tons.—*Queenslander.*

MESSRS. POWERS & WEIGHTMAN, the well-known quinine manufacturers of Philadelphia, U. S., have announced that they have made arrangements with the Fabrica Lombarda, at Milan, to manufacture quinine at these works during the rebuilding of their own factory in Philadelphia. Dr. John H. Weightman has arrived in Europe to superintend the manufacture.—*Chemist and Druggist.*

CACAO PESTS, TEA IN HAPUTALE, *ET HOC GENUS OMNE.*

We lately received from a correspondent the following letter :—

"I send by today's tappal in a box some cacao leaves on the underside of which are small insects which I imagine to be *Helopeltis Antonii* in an early stage of their growth. I showed some of them to three other gentlemen who have already given their view on the subject in the local papers, and have studied the insect in all stages of its growth, and they decide that it is not Dr. Trimen's *Helopeltis*. Not satisfied with their decision I send you these and would be glad if you could get somebody to indentify them, as their habits and effects on the leaves are so similar to the tea bug as described by Van Gorkom and other scientists. One of the gentlemen I shewed them to promised at my request to send some to Dr. Trimen three days ago, so I suppose we shall soon get his decision."

The box, containing the cacao leaves, came to hand safely, so we sent it on to our usual referee, who kindly replied as follows :—

"*Thrips* (in the immature and perfect states) described in 'Garden Pests' page 63. They are very injurious when present in large number. The remedies mentioned in the 'Garden Pests' would be difficult of application on a large and extensive scale. I have seen the pest on cinchona leaves sent from Nuwara Eliya."

The insects certainly were numerous enough on the leaves sent to us, but, as far as we could see, the leaves were in no way injured by them. The following is something of what is said about them in "Garden Pests" :—

Thrips adonidum. The troublesome little insects known as Thrips, comprise a small order named *Thysanoptera* (tassel-winged). They are minute insects seldom exceeding a line in length: they have the power of springing a great distance. We have found that these, like Red Spider, are best held in check by the free use of the syringe and clean water, and that the same general conditions favourable to Red Spider are also favourable to Thrips. Where they obtain a firm hold on the plants, much difficulty is found in getting rid of them.

The various remedies suggested are liquid insecticides, fumigation with tobacco, tobacco or snuff powder, sulphur and clay on hot bricks, sulphur dusted, white hellebore and *hot baths*!

We have just heard that coffee in Badulla is perfectly brown with "red spider" at present, but our informant also tells us that usually the trees most affected bear the largest crops, as the pests seem to have the same effect as drought upon the plants. We are sorry to learn that *Helopeltis* is doing great havoc among the cinchonas over in the principality. This is what is said in "Garden Pests" on red spider :—

Acarus Telarius. This is a minute mite, belonging to the family of spiders, *Holetra*. It is of microscopic size, and is just seen with the naked eye as a red moving speck. The genus to which it belongs (*Acarus*) contains an enormous number of species, mostly parasitic in their habits, either upon plants or animals. The present species mostly begins to attack exotics when they are young and tender. The female red spider deposits its numerous eggs upon the underside of leaves; they are exceedingly small, whitish, and scattered over the leaves. The larvæ, as hatched, resemble their parents, save in size; when mature, they are of a dark-brown colour and slightly hairy. Like spiders and mites in general, they moult several times before reaching maturity. They spin for themselves silken webs, which shelter them from the weather and other influences. The cause of red spider is a dry, arid atmosphere, and to keep these pests

down, the plentiful application of clean cold water is the best means. Soft water, in which a little sulphur soap has been dissolved, is a very good remedy.

With reference to the letter *in re* tea in Haputale, we would point out that the figures represent a yield of 460 lb. per acre per year. It does not seem, therefore, a very rash estimate to predict that every district in Ceylon, where tea will grow at all, may pretty safely count upon securing an average of at least 400 lb. per acre in full bearing.

The following extract from the *Indigo Gazette* gives an idea of some of the benefits which a railway brings with it :—

The railway now brings up about 85 maunds of bamboo leaves to Darjeeling every evening and retails them at six annas a maund. This is a great boon to the public, as the leaf cutters had it all their own way previously and used to cheat most abominably. Competition in another directions has done much public good. I allude to the Nagri farm. It has brought the Darjeeling butchers to their proper senses, and since the establishment of the Nagri meat has been coming into the town, the quality of their wares has certainly improved. The extinction of the bullock trains may also have something to do with this improvement in beef. The use of coal as fuel for the boilers of tea gardens, situated within easy reach of the various railway stations, is being rather extensively adopted. It has been found in practice that about 20 seers of coal will suffice to roll a pucca maund of leaf. As firewood has become difficult and expensive to procure on many gardens, the use of coal for fuel effects a considerable saving on many gardens.

CULTIVATION OF RHEA GRASS IN WYNAAD

About the end of last year, the home papers contained several articles on the cultivation and preparation of rhea, or China grass, and much information was collected and published on the subject, both by those who were interested in the cultivation, and by those who immediately deal in textile fabrics. All this public attention was roused by the invention, after half-a-century of enquiry, of a machine that successfully treated the raw material. A stimulus was given to mechanical genius in this direction, by the offer of a reward of £5,000 by Lord Mayo's Government in 1869, and England and France, and most of the countries of Europe, competed for the handsome prize. Several machines were put forward and tested, but none were considered to fulfil all the conditions of the advertisement, the most important of which was, that the machine should be able to deal with the grass in a green or freshly-cut state. The offer in 1869 was not the first official movement in this direction. In 1810, an effort was made to utilize the plant; and earlier still, in 1803, Dr. Roxburgh drew attention to the subject. The process of wetting, which was universally adopted to free the fibre of cementitious matter, was found to injure its color and durability, but no substitute for this insanitary and injurious process was found till Mr. Smith, an engineer in the Mauritius, patented a machine, which Messrs. Death and Elwood, the London manufacturers, perfected, and which is pronounced by competent authorities to be all that is desired for producing the fibre at one operation ready for the loom. Simultaneously, or, perhaps, a little in advance of this discovery, two French chemists, by a double patent, had arrived at a similar result, but their treatment was rather chemical than mechanical, and will be noticed further on.

Various other fibres, besides rhea grass, had been cultivated and tried in Southern India. Flax for instance, was introduced on the Nilgiri Hills in 1863, and proved a failure. The cultivation of the Nilgiri nettle, one of the most valuable fibre plants of indigenous growth in that district, was sought to be encouraged, and a free grant of land was given for that purpose, about the middle of 1863, by the Madras Government. The experiment was tried in the Coonoor ravine, on the site of the present Glendale tea estate, then known as the Vellanie estate. Mr. Sanderson, an engineer, was in charge of the enterprize. The nettle which luxuriates in the moist shade of the sholahs in the plateau was transported, when full-grown, to the site, and planted on the land; but the conditions not proving congenial, the transplants immediately died away. The promoter were not, however, to be deterred by the failure of a single attempt, and thought success might attend the experiment, if seed of the nettle was procured, and sown broadcast. This was accordingly done, but over a very large extent. Little more than half-a-dozen seedlings struggled into existence, and these refused to attain maturity, and soon perished for want of the protection of their natural *habitat*. Meantime, Mr. Sanderson was erecting a scutching machine to treat the stems when they should be ready. With the failure of the cultivation, the works were abandoned, and in 1864, the Government was made acquainted with the complete failure of the experiment, and lapse of the free grant. This Nilgiri nettle produces a fibre of great strength and lustre, and is exceedingly long in the staple; but the manipulation is troublesome, as the stems are covered with strong thorns, and the sting of the foliage is very painful, and the effects prolonged. The Todas prepare the fibre by a process of boiling, and sell it to the other Hill tribes, who use it in embroidery, after it has been dyed of various colors. The fibre has been from time to time exhibited, and attracted admiration, but the character of the plant, the scantiness of the supply, and the difficulty of the process of extraction have prevented any considerable quantities of this material reaching the home market.

The China grass, in a wild state, is to be found in many of the ravines on the slopes of the Nilgiris, and in the woods of the Wynaad. We hear that it abounds in the Tambrachery Company's property, and on the Glenrock estate, where immense quantities will be treated until the cultivated rhea is ready for the machine. The forest soils of the lowcountry, especially where facilities for irrigation exist, are specially suited to its growth. On the Glenrock estate, the cultivation has been commenced on a large scale. All the plants that could be obtained, have been secured from Bangalore, Sharunpore, Calcutta, Kangra Valley and Algeria. Ten acres of ground are already planted, and the propagation is being extended at the rate of about 5,000 plants per day. The growth from ten plants put out in January last has proved prodigious. It is proposed in course of time to put out 5,000 acres of land in Wynaad under fibre cultivation. Under the superintendence of Mr. J. W. Minchin, the experiment has every prospect of success. The same Company has purchased the concession from Government to Mr. H. P. Hodgson in the Bowany Valley, of a block of land, one-mile in width, on each side of the Bowany River, running up from Matoopolliam to the Koondahs, a distance of twenty-five miles. On this land there is growing an immense quantity of the "Marool," or "Sanseviera Zeylanica," or "Moorva" which is referred to in the following terms in Doctor Forbes Watson's lecture at the Society of Arts :—

"This plant grows as a wood in Madras, and other parts of India. In fact it is such a nuisance, that the people sometimes do not know what to do with it, but this machine (Smith's) tells us what to do with it. The sample which I hold in my hand, was prepared upon the occasion to which I have alluded. Here is a sample which is prepared on a commercial scale in India by this machine, and I may say with regard to

that particular fibre, that it has been proved, that it will compete fairly with Manilla hemp, which occupies a very important place in this market. Here is a sample of cord made from it, and you can all see how beautiful and white it is. This cord is made by one of the principal makers in the kingdom, and his report is, that it is 7·4 stronger than the best manilla, and over 4 per cent lighter."

The sample exhibited on the occasion was taken from two tons of this fibre prepared in 1882, by Messrs. Stanes & Co., of Coimbatore, which sold in London at the rate of £40 per ton. An expedition is now being arranged to thoroughly survey the Bowany Valley Ghaut, and arrange for the erection of the machinery, to treat the enormous natural supply of this fibre-yielding plant in that locality. The Glenrock Company has £35,000 of its capital still at its disposal, and is in a position to test the profitable cultivation of rhea grass with the best prospect of success. Systematic cultivation is, however, necessary to produce the best results. A light soil, lying over a deep permeable sub-soil, sandy but rich, naturally damp, or easily irrigated, is well adapted. Swampy or excessively damp soil will cause the roots to perish as they are very sensitive, and will rot in stagnant water. All these conditions are fulfilled in the Glenrock estate, which possesses variety of aspect, as well as diversity of soil, with ample facilities for irrigationn. —*Madras Weekly Mail*, 12th July.

In continuation of the remarks in our last issue, we may now say a few words on the profits of cultivation. For India there is nothing to guide us, as systematic culture has never been pursued, and data are wanting to frame an accurate estimate ; but all the authorities on the subject are agreed, that the cost in India is certain to be less than in Alegeria, where, notwithstanding the fact that land is more expensive, and wages high, the cultivation has proved to be remunerative. With land in Southern India, good, abundant, and cheap, and with the cost of labor almost nominal, there is no reasonable possibility of the cultivation proving a failure. Dr. Forbes Watson thinks that those who believe they are going to grow fibre for little or nothing are mistaken. It needs expensive cultivation, both manure and irrigation. All the authorities, however, are decided on one point, that in India the experiment will be carried on under the most favorable conditions. The cost of opening 500 acres of land is quoted at £10,000, or at £20 per acre ; and in this is included £8 for plants, an item which may be considerably curtailed by propagation which, as has been shown, can be proceeded with rapidly, and economically. Suppose we accept the cost of opening at the figure quoted, up-keep will not exceed £5 per acre, and will diminish with the age of the plantation, while preparation at the highest rate will not exceed another £5 per acre. In the topics four cuttings can be attained at the rate of, say, 250 lb. of fibre per cutting per acre, which is nearly at the rate of a ton of clean fibre off two acres per annum. The present price of marketable fibre is quoted at £50 per ton, and higher prices have been obtained, but in the prospect of extensive production, and a regular supply, we shall take no more than £30 as the selling price, which will leave a clear profit on the capital outlay of £10 per annum of every ton of fibre produced, or at the rate of £25 per cent, as a regular and steady return. Few other agricultural products can show such remunerative results, and no other cultivation needs so little special qualifications for carrying it on successfully. In allowing £10 for the cost of preparing a ton of fibre, we provide for skilled supervision, which is necessary to obtain maximun results from the machinery.

The patents provisionally secured for the Glenrock Company are :—

I.—Messrs. Death and Ellwood's machine (Smith's patent) for the decortication of every description of fibre-producing plant by the action of water.

II.—Messrs. Ekman's patent for the preparation of ultimate fibre from raw fibres, by boiling under steam pressure, in water containing sulphurous acid in combination with magnesia. Also for the conversion of all refuse into pulp for paper-making.

N. B.—The exclusive right to use the above machine and process has been secured within the limits of the south-east Wynaad.

III.—M. Favier's process for the decartication of rhea by subjecting the green stems to the action of steam.

IV.—MM. Frémy and Urbein's process for the treatment of textile vegetable fibres by subjecting them to the action of caustic alkali, and pressure in certain exact proportions according to requirement.

N. B.—The rights to use the above two processes have been secured for the whole of Madras, and for the Province of Mysore. The Lini Soie Syndicate are the vendors of the two latter patents, which are described as follows :—The green sticks of rhea, after being stripped of their foliage, are laid in a stout deal box, or trough, 8 feet long, 2 feet wide, and 20 inches deep. A false bottom is provided, inside which runs a ¾ inch perforated iron steam pipe connected with a steam generator. At one end of the trough is an outlet for the condensed water from the steam. The lid is closed, and steam turned on for 20 minutes at a low pressure. In that time the steam has acted on the gummy matter, which binds the epidermis to the woody stem, and dissolved it so completely, that the "ribands," which is the technical term applied to the fibre with the bark adhering, can be stripped off by hand. Here the first process, or decortication, the patent of M. Favier ends, and the second operation, the patent of MM. Frémy and Urboin begins, which consists also of a treatment with steam to further separate the epidermis and mucilageneous matter from the fibre or filasse. The "ribands" are now laid on metal trays, which are placed one above another, in a verticle perforated metal cylinder. When fully packed, the cylinder is placed within another strong iron cylinder, containing a known quantity of water, to which an alkali has been added. Inside the cylinder is a steam coil, which on steam being turned on causes the water to boil. The boiling is allowed to continue for four hours, when the cementitious matter readily parts from the fibre, on the mass being transferred to a centrifugal machine. The fibre thus cleansed, is laid in a bath of hydrochloric acid, after which it is washed in cold water, then in another acid bath, and finally in cold water, and dried for market.

The Lini Soie Syndicate contemplate granting advances on crop of ryots who would undertake the cultivation of rhea, and the employment of an agent to itinerate, provided with their steaming apparatus, to work up the material in the field. The time, however, has not yet arrived for the execution of this part of the programme. The ryot must have ocular demonstration of the profitableness and simplicity of the industry, before any general progress in the growth of rhea in the districts can be expected to take place. The Glenrock Company, now the transferees of these patents, do not propose to use them, until the cultivated rhea, for which they are specially adapted, is ready for treatment. Their attention will be confined to the treatment of indigenous fibres by the Death and Ellwood's Double Machine (Smith's patent) of which Mr. J. W. Minchin, their manager in this country, has brought out ten. The invention consists of an iron framing, about 3 feet high, 2 feet wide, and 3 feet deep, from front to back, provided

with a revolving drum, 18 inches in diameter and 12 inches wide. The drum is fitted with a series of beaters, which pass near to the edge of a feeding table, the drum being covered in by an iron hood. From beneath the feeding table a thin sheet of water is made to play in a constant stream, against the drum, at a certain pressure and angle. This constitutes the whole apparatus. The fibrous plants are fed in by hand, and are simply held up to the beaters by a cushion, or backing of water, by which means the fibre is freed from extraneous matter in a remarkably short time, and produce in excellent condition. The machine is suited to treat any description of fibre, and all are treated in the most perfect and satisfactory manner, no matter whether thick or thin, the cushion of water accommodating itself to the size of the material acted upon. A double machine will turn out from 140 to 250 lb. of clean fibre in a day, according to the skill with which it is used. Dr. Forbes Watson sets the cost of the mechanical process of cleaning a ton of fibre at from £7 to £9. The ten double machines on the Glenrock estate, will be driven by the power erected for working the quart-crushers, and there is ample room in the buildings for drying and treatment. The mills for the present will be kept employed on the indigenous jungle fibres of which, as we have stated, immense quantities are available throughout the Company's lands.—*Madras Weekly Mail*, July 15th.

TEA CULTIVATION IN UVA.

It is well-known that the gentleman who has a leading voice in the management of the two great Uva coffee companies decided strongly in favour of "going into tea" after a full examination of all the circumstances, including the soil and climate of the principality. It may not be equally patent that an agent of one of the greatest firms in London and the world, who have large interests in Ceylon, sent out here with *carte blanche*, decided that 2,000 acres of properties, a good proportion of which are in Uva, should be put down at once in tea. In an interesting and encouraging report from Haputale which we publish elswhere, our correspondent tells of the progress of cacao and tea planting in the district and specially mentions the flourishing condition of tea bushes growing on a piece of poor patana. They are laden with seed, and, if the bushes are enabled to elaborate seed from the poor patana soil, we need not doubt their powers of flushing should they be pruned and grown for leaf. But in talking of the cultivation of the patanas of Uva, we contemplated neither sterile nor poor patanas, but nooks and corners of low-lying, comparatively rich-soiled and sheltered pieces of grass land, of which tens of thousands of acres exist in the valleys which score the principality and which will yet be cultivated with cacao and tea. The grass-lands we refer to may not have soil quite equal to that of the grass-lands of Southern India on which tea and cinchonas flourish, but the climate of Uva is immensely superior. And let the fact be kept in view that even comparatively poor patanas can be rendered fertile by turning up and aerifying of the soil and the adding to it of the cattle-manure which can be procured in good quantity close at hand, not to speak of the artificial manures which the railway will carry up. Would-be-wise men, professing to be friends to Uva while they are really its enemies, may cant and sneer at the idea of patana cultivation, but we are willing to stake our reputation for observation and prevision on the assertion which we deliberately make, that, if the railway is only extended to Haputale, this generation will see many comparatively large tracts of patanas cultivated with cacao and tea by Europeans while native patches will count by thousands all around. There would be little difficulty in arranging that both cacao-beans and tea-leaf should be carried from the native gardens to central factories for curing.

BECHE-DE-MER SOUP.

[A good deal of *bêche-de-mer* being exported from Ceylon, our readers will be interested in knowing the uses it is put to.—ED.]

Sir,—In your answers to correspondents, 24th May, in reply to "X" you state: "The method of making beche-de-mer soup is known only to the Chinese, who appear unwilling to divulge it." This is not correct. The fact is, the class of Chinese who come to the colonies seem quite ignorant as to its preparation, and do not use it at all but export it all to China, where it is used only by the higher class. From what I can learn it is not made into soup, but boiled with fowl, pork, &c., and any attempts I have seen made by the Chinese merchants when specially asked resulted in a mess not at all palatable, the fish being in lumps. Beche-de-mer, when properly soaked and cleaned, is perfectly tasteless. It is pure gelatine, and I believe one of the most nutritious articles of diet known. The following recipe may be of use to "X" and others. I have seen it followed by several good Chinese cooks:—

For say ten persons make soup in the ordinary way, of beef, &c. Take two teat fish of good quality, or a corresponding quantity of black or red fish, soak in water from twelve to twenty-four hours, thoroughly scrape and clean from time to time, changing the water as required, as it swells greatly. The result will be a glutinous-looking mass, like lumps of jelly. Boil separately for five or six hours; take out and cut or mince up very fine. About a quarter of an hour before serving add this to the soup, and let it boil. There must not be any vegetables. Mince or egg balls are a desirable addition, also sherry, &c., to taste. This gives a body to the soup, which if left over will be almost a jelly when cold. I believe if this article became understood it would be used all over the world, especially for invalids, as it is very strengthening, and, although anything but nice looking in its dry state, it is a very delicate article of diet when properly treated. It makes a splendid addition to beef-tea, and I would call the attention of medical men to this fact. It is seen in the above form frequently used in the clubs and leading hotels in Melbourne and Sydney.—I am, sir, &c.,

THE WORKING EXPENDITURE OF COFFEE ESTATES.

The present state of the coffee market, and the inability of mercantile houses to advance against growing crops to such an extent as has been gone for some years past, is causing great anxiety to those of our community who are dependent on such assistance to work their estates. "It's an ill win that blaws nae body guid," and I feel sure that if the present serious crisis is met rightly much valuable experience at least must follow. I would refer back some twenty three years when coffee was £50 per ton; the rupee 2s 3d sterling, and the rate of interest charged on monies advanced for estate working 10 per cent. to 12 per cent. Against the above, we have now coffee £65; exchange 1s 8d; and interest on advances 6 per cent. Twenty years ago men worked their estates themselves, or by proxy; lived comfortably, and saved money, or extended their possessions from the profits at

the present time only ruin of the owner is prognosticated; a lesser alternative is hardly allowed to be possible. The question is, in what way were the estates worked to an advantage then? I reply, that a cooly was expected to do a fair day's work, and, as a rule, his employer was present to see that done, with like regard to quality and quantity. The cooly does not work now as then, but why not? He can and will, if such be insisted upon, and there is no doubt that the earlier all combine to give fair pay for only fair work the earlier will the change for the better result. I append a copy of an actual working estimate of 1861, Wynaad, and it will be noted that the figures represent a fairly liberal amount for the respective works. For this I am indebted to a lang syne acquaintance for preserving amongst his papers such testimony of the working figures of by-gone days and if the same, will in any way help any of my brother-planters over the stile of present difficulties the end of this will be gained.

OLD PLANTER.

Estimate for Opening 200 acres of Coffee Land in 1861:

Tools	400	..	..	500
Buildings	600	2,000	200	300
Roads	1,000	800	100	200
Nurseries	500	400	..	..
Felling and planting 100 acres at R40 ..	4,000	4,000	..	..
Superintendence ..	3,000	3,000	3,000	3,000
Contingencies ..	500	800	300	300
Cost of cultivating planted land ..	..	1,000	2,000	3,000
Pulp house, store Machinery ..	..	..	3,500	..
Picking, curing & transport at R100 p. ton	..	..	2,000	6,000
Rupees ..	10,000	12,000	11,100	13,500
		10,000		
Rupees			22,000	
			33,000	
To 20 tons coffee at R500 per ton			10,000	
		Rupees		23,100
				36,400
To 50 tons coffee at R500 per ton				30,000
		Balance to debit Rupees		6,400

COFFEE MAKING.

Last week I gave some remarks on "A Cup of Tea," with the chief reasons for its bad effects, which nearly all spring from some error of making. At present I purpose giving a few hints as to the making of coffee, which I hope may prove acceptable to many. Coffee properly made is a great institution; it is almost meat and drink. On a cup of good coffee taken with bread for breakfast, a man can work as hard as if he had had a heavy meal of meat. I believe if good coffee could be got, well made, and at a low price, it would take the place of the beer which is such a curse to Melbourne as to many other places, and would supply a temperance drink which is such a necessity to working men. On the continent good drinkable coffee can be got at the most obscure *cabaret*, but that cannot be said of Australia. As for the coffee to be obtained at the railway refreshment rooms and on the steam-boats, it is simply an abomination. To make coffee that is nourishing as well as palatable, you must attend to the following directions:—Mrs. Glasse in her old cookery book says "First catch your hare," so in making coffee you should first get your coffee, because a great deal of the stuff we drink is not coffee at all, it is a vile compound of chicory, acorns, and what not. Certainly a little chicory is an improvement, but the quantity should be infinitesimal; it adds to the strength, but at the sacrifice of the flavor. Then chicory is cheaper than coffee, and there is always the danger that coffee may be extensively adulterated with it. I would strongly recommend the practice of roasting coffee at home, though cooks as a rule steadfastly set their faces against it. Every continental cook and housewife roasts her own coffee, and the process is very simple. There are several machines for doing it, but what is generally used is simply the frying pan. The fire should not be too strong and the coffee beans should be stirred with a spoon, so that they may all get thoroughly roasted, until of a dark mahogany color, not black. They should then be taken off the fire and allowed to cool. Coffee should be freshly roasted, so it is well only to do a small quantity at a time. In some countries they pound the beans in a mortar instead of grinding them, but a small hand mill is not an expensive article and is most useful. Coffee beans improve by age, although they are not nice if roasted for a long time, and they should be kept in a dark place. In making coffee I believe that more strength is to be obtained by simple boiling than by any other plan, but beware of over boiling. The water must be boiling. If the coffee be put in all at once, the coffee pot or pan should be put on a gentle fire and merely allowed to come up two or three times to the boil, and each time quickly removed. Before being put down to settle, pour out a cup or two of the liquid and return it immediately into the vessel, or pour in half a breakfast cupful of boiling water. The vessel should then be put near the fire for five or six minutes, and gently poured out, or, what is better, strained through a fine filter or flannel bag into the coffeepot for the breakfast table, taking care not to shake it. Some people prefer adding the coffee to the boiling water by teaspoonfuls till it comes to the boil, and then taking it off at once. Professor Liebig, I believe, recommends boiling one half of the coffee for a few minutes, and then throwing in the other half without letting it boil. The former extracts the strength, and the latter preserves the aroma. For all ordinary purposes tolerably clear coffee can be thus got; but if extra clearness be required, then mash up a raw egg, shell and all into a soup basin full of coffee powder, and boil as before. In France they very generally merely filter, but the coffee is less strong. I shall only add two more hints and those are—(1) Put plenty of coffee in, and (2) always use boiling milk. The coffee must be strong to admit of hot milk, *i. e.*, milk just come to the boil, and coffee should be always taken quite hot.—*Leader.*

TEA—SOILS.

It is a matter of some astonishment that more attention has not been paid to the nature of soils most suitable to tea. What does an analysis of soil reveal to the planter? What new light does it throw upon the subject? What has Government done to assist in the way of enlightening us on the subject? The answer to these queries is the same, nil. When tea cultivation was first started, an idea prevailed that nothing but teelah or hill land would suit tea, and in many instances precipices were planted, and have been now, to a great extent, abandoned, and nothing but flat land will go down with tea speculators. So far as Assam, and in this we include Cachar and Sylhet, is concerned tea cultivation goes on lands situated at elevations varying from say 25 to 200 feet above sea-level, and as yet it would be impossible to say what elevation suited it best. When attention was first drawn to Sylhet as a tea-growing district, grave doubts existed as to whether the nature of the soil suited tea, but it has been pretty satisfactorily proved that it does, at the same time what conclusion can one draw when in Assam proper, several estates we could mention are situate along side "paddy lands"—and in several instances on which "*Paddy or Dhar*" has been cultivated successfully.

Turn again to Ceylon which, so far as one hears, turns out more tea per acre from abandoned teelah coffee lands than any Indian Tea Estate. Turn yet again to the latest "*jad*"—the low bheel lands, now being opened out in Sylhet and Cachar, and the question somewhat resembles the story told of the old woman who preferred the old days of stage coaches to the quicker locomotion of railways, because when you had an upset with the stage coach the result was only an injured limb or something of the kind, whilst in the case of a collision on a railway, the old lady wisely said, "*Where are you?*" The question of soils is one which puzzles any one who has visited the tea gardens, and an analyses conveys nothing so long as we are wandering in the dark, as we are now. It has been satisfactorily proved that tea will grow anywhere from 20 feet above "dhan field level" to some thousand feet above sea-level on the Himalayan slopes,* and not only grown, in the actual sense of the word, merely to exist, but what we mean is to be a profitable speculation, but we should like to see Government take a little more interest in the matter and appoint an expert to go into the matter. If we had in tea the same interests represented that the "rice goods" line has in the present Cabinet we would not only have the duty repealed, which would be a doubtful benefit to the planter, but we would have scientific experts of all kinds appointed in the interests of the industry, but clothed in another robe, and assumed probably to be necessary in a sanitary point of view.—Exhibitions of all sorts seem to be the rage now-a-days, would it not be possible to get up an Inter-District Exhibition, and educate the public taste in pure Indian teas, and such as can find their way to the consumer, and not such trumped up samples as were exhibited at the Calcutta Exhibition.† If only we can excite sufficient interest and attention it would not be long before scientific knowledge would be brought to bear upon tea, and then would not have so much of the miserable failure of prospectuses as is to be but too readily met with amongst the many tea plantations held out to speculators. It is, we suppose, natural for tea planters to take shares in many of these tempting looking speculations, but it is wonderful how few are carried out on their original programmes. So far we confess we could offer no opinion on what soil is best suited to tea, as we have seen it flourishing on such entirely different soils, that it would appear to us as if much more depended on the manager than the soil that the thing should be a financial success.‡ At the same time we are far from thinking that a great deal is not yet to be learnt from science being brought to bear upon the subject. How many and how varied are the opinions we leave our readers to record, but every one in the tea districts knows that, until quite lately, the tea plant was considered pre-eminently a tap-root plant, and when one planter was asked by another to explain certain deficiencies in yield, was answered that it was entirely due to the plant being unable to penetrate the hard sub-soil from being originally badly planted. How rudely may we ask has the idea been dispelled by the bheel planting, in which no tap-root exists ‖ and yet gives a magnificent yield per acre, and the old woman's question again affords an answer—"Where are you?"—*Indigo and Tea Planters' Gazette.*

THE SUGAR INDUSTRY.

It may be said of the sugar industry at the present time that it is on its trial in Queensland. The same might have been, and no doubt was, said of it some years ago, before it emerged from its experimental stage into one of apparently well-established success. The remark was true then, but only in a local and limited sense. It is equally true now, but its application has a wider—a national—character. When the cultivation and manufacture of sugar began to be successfully conducted, there was no difficulty to contend with on the score of labour. Coloured labour could be procured from the Pacific Islands without any great trouble: there was no uncertainty about it, because there were quite enough men who were willing to come over, and the cost of obtaining and placing them on the plantations was moderate. So completely successful, indeed, had the planters' operations become that capitalists in the Southern colonies, who were just then beginning to feel the difficulty of investing their accumulating wealth at reasonable rates of interest, began to turn their attention to this new field for enterprizing speculation. No sooner, however, had the rush for sugar lands fairly set in than the labour question presented a new aspect. The number of recruits who were wanted to carry on the work, consequent upon this extension of cultivation, could not be obtained, and the cost of procuring field hands rose in a proportionate degree to the obstacles which had to be surmounted before they could be secured. Kidnapping and other illegal means were more frequently resorted to, and the regulations were made more stringent. Then came the general elections, the Liberal party advocating the total abolition of black labour; and it was the Liberal party who gained the victory. Coloured labour has not been abolished; but the conditions under which it may be obtained and used are such that many persons who have carefully watched the course of events do not hesitate to affirm that it must shortly die a natural death. Be that as it may it is plain to everyone that sugar can only be made at a much greater cost now than a few years ago. And when, in addition to these circumstances, we find that the value of the commodity has declined, and that no solution of the labour difficulty has even been attempted, the truth of our contention must be admitted—the sugar industry is indeed on its trial.

* * *

Amongst the causes which are likely to encourage beet growing, must be quoted the following—"It is said, for example, that the intensive cultivation necessary for growing beet so improves the soil in Germany that for four years afterwards all the crops raised are greatly improved. Consequently the cultivation is much in favour with good farmers. And, besides, the pulp of the root, after the juice is expressed, is used in the feeding of cattle. For these reasons beet cultivation will probably continue to extend upon the Continent for some years yet, even if the price remains low, and will increase rapidly if the price rises; while here at home a movement is just now being set on foot to introduce the cultivation in England.

Enough has been said to show to what degree the extension of sugar-growing in Queensland is affected by the condition of the industry in Europe and elsewhere. It has been admitted on all hands that the interests of the colony have been already, and may be further, advanced by the expansion of the sugar trade. We would ask then—Is this a time to make what may become a great industry, which will greatly enrich the colony, subservient to the exigencies of party politics? Should not everyone rather devote himself to its encouragement by every legitimate means, instead of allowing it to languish—perhaps almost to perish—while politicians squable over questions of black and white, and while the labour question is really finding, for good or for evil, its own solution?—*Queenslander.*

ABSORPTION OF WATER BY PLANTS.—Mr. T. Darwin, in an article in *Nature* (May 1, p. 7), on the "Absorption of Water by Plants," shows that the rate of absorption is influenced by the dampness or dryness of the air, being more rapid in dry air, owing to the more rapid evaporation from the leaves, and more rapid in sunlight than in shade. He also confirms Baranetzky's statement that a small disturbance, such as a slight shake, by increasing the transpiration from the leaves increases the rate of absorption, while cutting off a twig rapidly diminishes it. A. Sorauer, however, found in some experiments on gourds that the removal of leaves from plants on two occasions did not alter the amount of evaporation in the least; and even when half the leaves were removed from another plant, although a reduction in the amount of evaporation ensued at first, after eleven days the evaporation was equal to that of an untouched plant (*Journ. Chem. Soc.*, xlvi., 627).—*Pharmaceutical Journal.*

THE JUICE OF THE PAPAYA FRUIT.

A correspondent has been good enough to send us the latest information regarding this fruit and its uses, as follows :—

"Papaïu, papaïnum or vegetable pepsin may be prepared from the juice of the green fruit of carica papaya by adding alcohol, which precipitates papaïn. This precipitate is dried and powdered, and is then quite ready for use. Brunton considers that, in its peptonising powers, it is superior to the ordinary animal pepsin, and it has the additional advantage of neither requiring the addition of an acid nor an alkali to convert the contents of the stomach into peptone. It is extensively used both in France and Germany, and has been given with good results even to children. It is an invaluable remedy in the dyspepsia of those recovering from attacks of cholera. No planter upcountry should have any difficulty in preparing it. It should be thoroughly dried in the sun on a hot-plate and preserved in well-stoppered bottles. In France, it is mixed with starch to preserve it, and is often made up in the form of papaïn lozenges, 'Dragées de Papaïne,' of which two form a dose. The 'Syrop de Papaïne' is also a favourite form as well as papaïnwein and papaïn elixir. The alcoholic preparations of it are the most popular. This vegetable pepsin is said to digest the tapeworm in the intestines, and the juice of the carica papaya is a favourite domestic remedy for the expulsion of that worm in Brazil."

THE TEA TRADE.

In reply to an article that appeared in our contemporary the *Standard* "The Owner of a Sensitive Tongue" writes:—The day has gone by for excitement over the first arrivals from China. Buyers and sellers would be only too thankful could the market be opened a month or two later, instead of in the middle of the holiday, or "slack" time, as we call it. It would be a good thing for the British producers in India and Ceylon if the public could be taught to discriminate between good and bad tea. Why a man should boast in his dining-room of the price he pays for his claret, while in his drawing room his wife boasts that she gets her tea for next to nothing, is a mystery. Good tea is not sold for nothing in Mincing-lane, I can assure you, and the matron who thinks she can buy the real thing at a low price displays a credulity about tea which does not characterize her in other matters. You must allow me, sir, to take exception to your dictum that a taster's palate wears out in eight years. Mine has had more than the average amount of work for fifteen, and is good for another fifteen years, I hope. Our digestive apparatus and our stomachs, alas! wear out too soon, and we fly for relief to Cavendish-square. And then you advertize that we are highly paid! I can assure you we do not think so. Pray, sir, contradict the report, or the market will be overstocked with would be tasters. Like poets, great generals, and R. A.'s tea tasters are born, not made.—*London and China Express.*

THE HON. SIR V. NAZ'S REPORT ON LABOUR.

[It is curious that with so large a number of Indians resident in Mauritius the labour difficulty should be the subject of constant complaint. But the following extract will shew that the former coolies were becoming landholders on their own account.—ED.]

The Hon. Sir V. Naz's "Third Interim Report" as chairman of the committee of the whole Council on the supply of labour and the cost of production of sugar is remarkably well drawn up and lucid. Every point which can in any way bear upon the subject has been taken up and well reasoned. The total male Indian population has in 18 years 1867 to '84, decreased by 10,000, in round numbers from 157,000 to 147,000; the deficit has been partly made up by 11,000 creoles of *Indian* extraction engaged under written contract; but the tabulated statement of old and other immigrants under engagement gives only about 37,000 of the 147,000 male immigrants in the Colony—shewing some 110,000 who are not engaged; who are occupied in small culture, and as hawkers, those who work on estates without contract, servants and workmen, and others having no regular occupation.

We must however not overlook the fact that the said 147,000 male Indians include some 50,000 boys from 10 to 20 years of age; but again that total number comprizes more than 10,000 above 55 years of age, the ages of these latter may be compensated in some degree by some of the 50,000 boys.

The Report says that the increase of the total male population of Mauritius (i.e. of all nationalities) has been in the last 14 years only 3,224. The number of children from 1 to 10 years has increased by 7,611. The aged Indians above 55 years have increased by 5,127, whilst the number of adult Indians has decreased by nearly 12,000. Here we shall copy a paragraph of Sir Virgile's, as it is so well expressed.

"The consequence of which is that employers with money in their hands, cannot, even at an excessive price, get the labour which they absolutely want; it becomes evident that, however desirable it may be to restrict vagrancy and desertion and to induce, by fair and just means, the Indians now in the Colony who can be efficient labourers, and who do not work, to become industrious and to earn an honest livelihood; the time has certainly not yet come when this Colony should try to secure the return to India of the new immigrants whom it may introduce for some years to come, so long as they are young and strong enough to be efficient labourers."

A large number of Indians and Indo-Mauritians are gradually becoming small land-owners. The epizootics having destroyed so many of their mules and cattle, they considered that plots of land were a much surer investment. The Report tells us that the Transcription and Registration Office is at the Committee's request preparing a tabulated statement of the number of Indians who have purchased and leased land. It is thought that there are at least 10,000 Indians who have done so.—*Mercantile Record and Commercia Gazette.*

BARON LIEBIG'S MALTO-LEGUMINE COCOA AND CHOCOLATE WORKS (LIMITED), BERMONDSEY STREET, LONDON.

It is now some fifteen years ago that the late Charles Dickens left it upon record that "to convince an untutored, or even a semi-educated person, that nearly all the merits of a juicy or a succulent steak may, by judicious cooking, be derived from the humble bean, the disregarded oak-mushroom, or the despised onion, would be a task not much less difficult or arduous than was Galileo's persistent demonstration that our earth is round;" yet, in these days of experimental hygiene, a mighty effort is being made to change all this, and the present International Health Exhibition is a grand example of the truth of our remarks. Amongst the food exhibits we notice with considerable interest samples of leguminous articles of diet prepared at the Baron Liebig's Malto-legumine Cocoa and Chocolate Works (Limited), Bermondsey Street, which are destined doubtless, to take a somewhat prominent position in altering the traditional standard by which in the past the relative value of nutritive substances has been established. The company carrying on these works was formed in order to acquire the exclusive right to manufacture and to sell Baron Hermann von Liebig's malto-legumine, and also his leguminous cocoa and chocolate, not only in the United Kingdom, but also in all the British colonies, dependencies, and possessions. Now, the name of Baron Liebig has long been before the public, principally in connection with improvements in our food-supply, and it is, perhaps, not too much to say that no name has ever stood higher in the

annals of the application of scientific chemistry to food products than that of the late Baron Justus von Liebig, and we are told that his son, Baron Hermann von Liebig, is following worthily in the footsteps of his father. So many, however, have been the imitators of this illustrious chemist's name, that the present Baron has found it necessary to give special notice that, with the exception of the company at present under notice, and the Liebig's Extract of Meat Company, which acquired the right to use the name of Liebig from his father, no other individual or firm has the right to employ the name these two being the only articles which were and are subject to his constant personal control. At the Health Exhibition the company are showing samples of their leguminous cocoa, malto-leguminous chocolate, and malto-leguminous flour, and, doubtless, our readers would naturally like to know of what ingredients these specialties are prepared. "This, however, is one of the few things," as the chairman remarked at a recent meeting of the company, "as to which it is not yet considered expedient that even the shareholders themselves should be enlightened. The preparation of malto-legumine is a strict secret, and even the process of manufacture is said to be known by only two or three persons in the United Kingdom, and these are bound under heavy penalties not to disclose the secret." It must suffice to say that it is claimed to be "a method of preparing a leguminous product in such a manner as to render it superior as an article of diet to any other food, natural or artificial yet brought before the public; the superiority of the digestibility of malto-legumine being evidenced by the fact that 90 per cent. of it is easily assimilated by the weakest stomach." All three preparations have been before the public long enough to acquire considerable favour, and the list of testimonials which the company possesses indubitably proves that each and every one of them is attaining a growing reputation as a light and nutritious restorative, digestible alike by young and old, and especially so in sickness, or in cases in which the powers of the stomach may have been weakened or partially destroyed.

[Legumes are excellent as food, but we can scarcely approve of the attempt to pass off beans as a substitute for cacao. Our readers are, of course, aware that "Revalenta Arabica" is essentially flour of lentils.—ED.]

COCONUT FOR TAPE-WORM.—Dr. Martiali says, in Annales de Med. Navali, that this remedy has been known to the Antilles since the time of the aborigines. The nut is grated and eaten slowly by the patient. After three hours a dose of castor-oil is taken, and the worm will pass away after five or six hours.—*Cor.*

INDIAN ECONOMIC PRODUCTS.—As we stated some time ago, Dr. GeorgeWatt, of the Bengal Educational Department, is engaged under the Revenue and Agricultural Department of the Government of India in preparing a dictionary of the economic products of this country. The want of a comprehensive dictionary of useful products is one indeed which has long been felt both by officials and commercial men in India. The opportunity has therefore been taken by the Agricultural Department to continue the work begun at Calcutta, and one of the most useful results of the Exhibition may be anticipated to be the completion of the dictionary which Dr. Watt has in hand. A collection of products to correspond with and illustrate the dictionary is simultaneously being brought together in the office at Calcutta, under the general supervision of Dr. Watt, by Teloknath Murkherji of the Agricultural Department. It will be made, we understand, on a sufficiently large scale to provide duplicate sets for provincial museums and foreign exhibitions. The dictionary, we are told, will probably be completed within three or four months, or within less than two years from the date on which Dr. Watt commenced his duties; and if this promise is fulfilled, the result will be very creditable to the author. The work is one which necessarily entails considerable labour and scientific knowledge. Dr. Watt has, however, been very cordially supported by the superintendent of the Imperial Press at Calcutta, who has already bestowed the utmost pains on the printing of the preliminary proofs, and has given assistance, without which the early completion of the dictionary would have been impossible. The work will be published in three volumes, and is intended to contain information obtainable about every economic product available from every known source, and to comprise also statistics of the production and commercial movement of each product up to date. If these intentions are carried out, the dictionary cannot fail to be a work of much utility both in India and abroad.—*Pioneer.*

FABRICS FROM WILD PLANTS.—In a shop window in New York city is displayed a variety of hanks of thread, some coarse, some fine, some dark-coloured, some light, some vari-coloured. Some of the thread has the softness of the finest silk, some is rough and raspiug as hemp. It is a curious assortment and attracts the attention of many a passer-by. A visit to the inside of the shop is a revelation of a coming revolution in several agricultural products of this country hitherto considerd useless. In a rear room, about 16 feet by 20 feet, were three or four heavy, but apparently simple, machines operated by a small steam-engine. The room was half filled with many kinds of weeds, weed-stems and leaves; while in one corner were seen barrels of crude asbestos. One machine was being fed by a young man, who gave to it bundle after bundle of the dry, brittle weeds, while another was greedily devouring asbestos, crushing lumps weighing three or four pounds, and swallowing them with a groan. The dry, trash-like stuff fed to the first machine was converted in a short time into the coarse, brown thread seen in the window, while the rough asbestos quickly changed its mineral hardness, and became a fibre as fine as silk, ready to be spun and woven. The common cotton stalk, which the planter of the South pulls up and burns after the year's picking, was made into a coarse thread, equal in every respect to the jute of India, which the United States buys to the extent of 6,000,000 dols. annually. Flax straw, which grows in many States of the Union, which is cultivated by hundreds of thousands of acres for the seed alone, and is burned, or left to rot in the fields, was converted into a fibre which made an excellent and strong coarse linen, and which, when mixed with wool in the process of manufacture, made an excellent substitute for cotton. Other plants, of which the greater number were discovered to be weeds of the commonest variety, were shown to contain valuable fibre. Among them were bear grass, Spanish bayonet (needle), okra, nettle, ramie, pita, baurbor, wild coffee, the cotton plant, and jute. Most of these plants grow wild. Little or no attention has been paid to their culture. From these various fibres, many of which, by actual experiment, will dye beautifully and perfectly, and without injury, can be made bagging, mats, matting sacks for grain, rope, cordage, twine, packing thread, paper stock of the finest quality, costly fabrics for wear, substantial fabrics for everyday use, and material for upholstering purposes. From the fibrous mineral asbestos can be made fireproof curtains and haugings for halls and theatres, fireproof ropes, carpets and ground work for oilcloths, and many other articles of luxury and necessity. Ramie and Sisal hemp fibre may be mixed with silk in manufacture, and common American grasses are turned into fibre fine and strong enough for wigs and false hair. Even the hard shell of the coconut is discovered to contain a fibre which closely resembles hair. It will not "pack," and is equal to curled hair for unholsterer's use. Indeed, there are few of our native products which do not contain some quality of fibre, and recent experiments have demonstrated that the United States pays annually for products which may be made at home the large sum of 16,000,000 dols.—*New York Tribune.*

CINNAMON WEIGHTS.—A London firm, referring to a cinnamon proprietor's inquiries as to the loss of weight in cinnamon, says :—An idea appears to be current among some that the loss in weight shown in account sales is due either to excessive samples being drawn, or to carelessness in preparation for sale, which is quite a mistake. As a matter of fact, the weight of samples drawn does not on an average exceed ¼ lb. per bale, and the loss of weight as shown by the landing account which represents the weight of the bales as they are landed before being manipulated at the Docks, and the re-weight account which is taken after the goods are sold, is very trifling indeed. An account of a parcel of 76 bales taken quite at random shows that the re-weight is in excess over the weight shown in the landing account, which proves to us that the loss of weight must take place on the voyage home owing to drage or some other such cause—always supposing the shipping weights are correctly taken. With reference to the proposal that every bale should not be worked—only one bale of each quality being opened, we fear the trade would not buy on such terms. If the prejudices of the buyers could be overcome, and they were persuaded to purchase on these conditions, no doubt a saving in the expense of preparing for sale would be effected, but we doubt whether you would not lose more in price than you would save in charges by any attempt to bring about such an arrangement, even supposing that it was possible to sell at all."—"Ceylon Examiner."

RHEA FIBRE is thus noticed in the proceedings of the Horticultural Society of India :—

Among other applications for information under this head, the following was received from Messrs. Begg, Dunlop & Co. :—

"We beg to send herewith a small tin containing a sample of Rhea fibre, made from Rhea plant grown in Assam, and manufactured by a New Zealand flax-dressing machine. Will you kindly have this examined by an authority, and let us know his opinion of it as also its commercial value? Any hints you can obtain for us as to planting, growing, time of cutting, etc., would be most acceptable, as the gentleman who has sent the sample has only grown a little as an experiment."

The sample was submitted to the Fibre Committee, and the following report was kindly furnished by the president:—

"I have carefully examined these samples of Rhea fibre. I am of opinion that in their present form and condition they are of little or no commercial value.

"The utmost possible care and attention are required in the manipulation of the cut stalks of this plant, with a view to separating and preparing the fibre therefrom. These samples exhibit a want of the requisite knowledge and needful care in their preparation to make them sufficiently valuable and attractive to the trade, which hitherto has been confined to the Home markets.

"I advise that further samples should be prepared and submitted, that in doing so all particles of bark, hard conglomerated pieces of gummy, mucilaginous matter, be avoided, and kept out of the sample, and that some data should likewise be afforded as to the weight of the stalks which have been operated upon, the quantity of fibre extracted, and the cost of doing so, all such information being essential if an experiment is to be of any value for future guidance." W. H. COGSWELL.

THE SAGO TREE.—We find the following interesting particulars regarding the sago tree in the Amsterdam *Handelsblad* :—"In Liak and Kumper the *rumbia* or sago trees, which grow luxuriantly in some districts, yield an important trade product to the inhabitants. The sago obtained from them is more in demand than tapioca flour, and will also find readier sale, from its being serviceable not only as food but also for making starch. In the islands of Tching, Tinggi, and Merhan, extensive sago plantations may be found which, at little expense for up-keep, bring the owners large profits." When it is taken into account that full grown trees—those that have attained a growth of from 7 to 8 years—find a ready sale at a Mexican dollar each, and that by means of imperfect appliances two or three dollars worth of sago is secured therefrom, it will be easily seen what the profits may be when sago is prepared on a large scale by machinery. Should the European market become available for large consignments of this product, sago-growing will become a very important and profitable investment. Unless we are misinformed, sago cultivation on a large scale has been undertaken in the Straits Settlements, in consequence of the terrible depression in the tapioca trade.—*Indian Agriculturist.*

THE FIBRE COMPANY'S MACHINE.—After writing our recent notice (p. 108), we received a specimen of the beautifully clean and strong fibre of *Sanseviera Zeylanica* (Tamil "marul") cleaned at Coimbatore by Smith's patent scutcher, and which sold in London in April 1884 at £40 per ton. There can be no doubt that the machines clean the fibres beautifully. But the question is a commercial one as to the quantity per diem which can be cleaned, and we do not anticipate any sale for machines here in Ceylon until those interested in getting them disposed of, give practical proofs of their capacity, such as was given recently in the case of Jackson's Hand Tea Roller.

CEYLON-GROWN PEPPER.—A specimen of "white pepper" grown on Lunugala estate, Rangala, has been sent to us, and two authorities pronounce it good. One writes as follows :—"The sample of white pepper is good, but the grains are small. All peppers, both white and black, have, during the last three or four years, advanced in prices very much—I think from exceptional causes such as the Acheen war. In June 1880, Singapore and Penang black was selling at about 3⅜d to 4d per lb. in London, and white at 5½d to 6d per lb. In June 1881, prices had advanced to 5d to 5½d for black, and 7d to 7½d for white. In June 1882, black was worth 5⅜d and white 9d per lb. In June 1883, prices were the same as in the previous year. This year, the price of black advanced to about 6½d and white 9½d to 10½d per lb. ! For several years prior to 1880, the normal values of Penang and Singapore black and white pepper were 3½d and 5d to 6d per lb. respectively." As there does not seem to be any immediate prospect of a cessation of the wretched conflict between the Dutch and Malays in Acheen (the point of Sumatra nearest Ceylon), we fancy the cultivation of pepper in Ceylon, if carefully conducted, might result in profit. Kapok trees are excellent supports for the vine.

THE THEOBROMA CACAO.—In a short time the [Regent Park Botanic] gardens will be in their full beauty, and visitors and students alike may delight in their green attractions. At the present moment the plant from the seeds of which cacao and chocolate are produced is a great object of interest. The *Theobroma cacao* is a native of tropical America, and, though it has been grown as a curiosity here and elsewhere, the first example of the fruit coming to perfection in this country may be seen at the Regent's Park. The two specimens in the orchid house are only a few feet high ; the flowers are in great profusion, seated on the older branches, and spring directly from the bark in clusters. By means of artificial fertilization several fruits have been set, and one has nearly arrived at full growth, but the colour, owing to insufficient sunlight, has not been fairly developed. However, observes the secretary, to have struggled through all the adverse conditions in which it is placed, and to have arrived at its present state, although perhaps not perfect, causes it to be more admired by Englishmen, who, one and all glory in success under difficulties. —*Chemist and Druggist.*

MANGOSTEEN OIL.

The seed of the *Garcinia Indica* yields a rich oil of great purity. This tree is indigenous to the western districts of India. It grows in the region known as Concan, between Goa and Daman. The *Corps Gras Industriels* describes as follows the mode in which the oil is obtained:—

The seeds are dried in the sun during several days, and are then crushed and boiled in water. The oil which escapes rises to the surface, and in cooling forms a solid crust. The yield is about 10 per cent. The product in its rough state requires to be purified, and for this purpose is melted in a steam bath, being afterwards filtered. It is then perfectly transparent, of a straw color, and at a temperature of 5·5°C. it forms a crystaline mass.

This oil is principally composed of stearic acid, with lesser quantities of myristic and oleic acid, the whole combined with glycerine. It easily saponifies, and produces a fine hard soap. It is soluble in ether, and slightly so in rectified alchol. If kept for too long a time it assumes a rancid and disagreeable odour and a brownish appearance.

It is found in the bazaars of India in the form of oblong pieces measuring about three and a quarter inches by one and a-half inches, and weighing about four and a half ounces. It is whitish, solid, dry and friable, but greasy to the touch. It is employed in India for the purpose of adulterating *ghee*, and recently Europeans have employed in for pharmaceutical preparations. Its relative scarcity does not allow of its use in the manufacture of soap and candles, for which purpose it would be a superior article. —*Independent Journal.*

DISEASE OF PALMS.

In the course of last summer we received from different persons diseased plants of Corypha and Phœnix, the leaves of which were covered with brown patches. Herr Professor De Bary, of Strasbourg, had the kindness to examine them, and the following is the result, which we now publish:—

"The diseased plants of Corypha australis which you sent to me at the end of October were a long time under examination by us before we could say anything about them. That is the reason the answer has been so long delayed. The browned dead portions contained all sorts of fungi (moulds), but quite preponderating, as further examination taught, was the species Pestalozzia, related to, and similar but not identical with P. macrospora, Ces. If the brown spots were made moist the spore-forming organs of the mould appeared on the surface in the form of black patches, as the enclosed sample indicates. When the moulds were distributed on healthy leaves that were cut from the plants and kept in a moist state the fungus pierced them and caused their death. According to the degree of dampness so spread the destruction over a greater or a lesser area. Whether the fungus is capable of killing perfectly healthy seedlings that are not kept too moist was not determined. From those plants which were sent, and which were grown on, all died except one. This has a leaf on which the Pestalozzia has appeared, and which is now partially dried up. The dying symptoms made no further progress in winter, and the plant is pushing out sturdy new foliage. Healthy seedlings of Phœnix dactylifera and of Chamærops were not attacked by the fungus even under quite moist culture under bell-glasses. On saccharine mixture and similar inorganic substances the Pestalozzia grows extraordinarily luxuriant. What most concerns us is the destruction of the fungus. The attacks are most probably invited by the not quite normal formation of the Corypha seedlings, or at least assisted hereby."—A. DE BARY in *Deutsche Gärtner Zeitung.*

THE ECONOMICAL PURIFICATION OF OILS FOR CULINARY USES.

The *Corps Gras Industriels* remarks that linseed, colza, poppy, and other oils are often used to replace others of higher value. The disagreeable odour of some of these oils (even when freshly made), probably arises from the seed itself not being fresh, and consequently not yielding a fine oil. The disagreeable savour is principally due to the presence of fatty acids. Small quantities of albuminoid substances, viscous bodies, and other impurities, finely divided, are also suspended in the oils, tending to form acid and volatile compositions which give to the oils a disagreeable odour and savour.

Experiments made with coconut oil have proved that the acrid savour can be removed by washing with carbonate of soda. No process can remove its peculiar odour, but as this is by no means unpleasant, there is no necessity for doing so.

The simplest way of removing the disagreeable savour is to melt the oil on a bath of water, and to add a solution of 2 per cent of carbonate of soda, and 10 per cent of chloruret of sodium in 50 per cent of water. After having turned it during some time, the fleecy precipitate is removed by filtration. If in shaking the oil (together with alcohol to which a small quantity of litmus has been added) there is still produced an acid reaction, the operation is recommenced.

The filtered oil is then washed with hot water, or boiled in salt water, in order to remove the last traces of soap and albuminoid substances, etc. Salt is used to prevent the oil forming an emulsion with the solution of carbonate of soda, and to raise the temperature during ebullition.

Neither the washing of the oil with borax, nor its treatment with chlorine or bichromate of potash and hydrochloric acid produce any effect.

It is, however, evident that a better product can be obtained with fresh seed and by purifying the oil immediately. By putting the oil into tin vessels, or into glass vessels hermatically closed, it can be preserved without becoming rancid.

The above process is applicable to almost all vegetable oils, and to cotton oil if the quantity of carbonate of soda is proportionate to the quantity of free acids contained in the oils. The advantages which are possessed by other reagents have not yet been determined.—*Independent Journal.*

AGRICULTURE IN PARAGUAY.

Consul Baker, of Buenos Ayres, states that one of the most valuable crops of Paraguay is tobacco; in 1829, its production amounted to only 2,675,000 lb., while in 1860, the crop amounted to 15,000,000 lb.; but the war with the allies almost ruined this source of wealth. It has, however, somewhat recovered its importance, the exports alone last year amounting to 8,975,000 lb. A large proportion of the crop is annually worked up into cigars, a branch of industry which is almost entirely in the hands of the women. The tobacco planted in Paraguay originally came from Havana, with the exception of a particular kind, which is called in Paraguay blue tobacco, *peti-haby*, the origin of which is unknown. The favourite leaf is a yellow tobacco, *peti-para*, grown chiefly in Villa Rica, which possesses about 6 per cent of nicotine. Sugar-cane is another of the important agricultural products of the country—a plantation of which sometimes lasts, without any care or necessity of replanting, for ten or twelve years. It is estimated that one acre of the cane will produce about 250 gallons of molasses. Rice also is extensively cultivated, and also Indian corn. Coffee is largely grown, and is regarded by some as the crop of the future. The crop which is most esteemed by the Paraguayans is the mandioca, it being with them an article of prime necessity, taking the place of wheat-flour in the family household; the tuber is also used as a vegetable. The quantity of land now under cultivation is very small, compared with the amount before the war with the allies, the great scarcity of labourers in the country very seriously retarding the development of the agricultural interests. At the present time there are 450,650 acres of land under cultivation, of which 210,000 are under corn, and 126,000 under mandioca. In Paraguay the cotton plant grows spontaneously, growing very rapidly, and lasting for ten or twelve years. The orange groves are scattered indiscriminately all over the country, the plantations attaining an immense growth, and the forests are everywhere full of the orange trees from the casual dropping of the seed. The fruit has come to be not only an almost indispensable article of food, but its annual exports exceeds 10,000,000 of oranges, chiefly destined for Buenos Ayres and Montevideo. The most important production of the country is stated to be Paraguayan tea or *yerba maté*, which in former years, by its

preparation for market and exportation, yielded the greater portion of the national revenue. The exportation of this article has increased from 4,000,000 lb. in 1861 to 11,375,000 lb. in 1882.—*Journal of the Society of Arts.*

BURNING VEGETABLE MATTER.

It is surprising to anyone who intelligently considers the subject what an amount of injury is recklessly done to the soil continually by burning off waste vegetable matter. The motives which cause it are various, some cultivators maintaining that the soil is too rich and must have its fertility reduced to make it yield well, and that it never can be exhausted; others doing it simply because it is the readiest way of getting rid of an incumbrance, and thinking it is no great loss. These impressions are very erroneous, and, if they did not involve serious and mischievous results, we might be content to look on complacently and smile at them. But they are more than mischievous, for they are more frequently than otherwise ruinous. Vegetable matter in a decomposing state in the soil helps very much to retain moisture, and also tends to attract moisture and fertilising material from the atmosphere. Moreover, such material wonderfully opens and lightens the soil, and therefore it operates mechanically, by improving the texture of the soil, to increase its growing and bearing capacity. The main reason why scrub lands are so immensely superior to open forest country is because they have so great an advantage of it in humus or decayed organic or vegetable matter. These facts speak loudly and for themselves. No farmer or gardener who is at all observant of things around him can fail to see them on every hand; and how in the face of all this the idea can be entertained that burning waste vegetable matter is no loss, it is difficult to comprehend. There are many cultivators of even our richest lands who know by experience that manure will increase the yield of such land; and, if so, how can it be advantageous to impoverish the soil by such wasteful methods? That burning speedily weakens the carrying capacity of land is apparently in the now exhausted wheat lands in South Australia and elsewhere, which cannot be coaxed into producing a fair average crop. The practice is wrong, and is at variance with science and experience; and therefore the fact cannot be too strongly insisted upon, or too often repeated, so long as it is persisted in by those who have to live by the produce of the soil. We should like to see cultivators storing all the waste produced from the land with an eye to returning it in some form, either improved by being used as bedding for stock, or stacked to hasten decomposition, so that it may be restored to the soil from which it sprang. There is no such thing as intelligent farming without it, and, unless the practice of burning is speedily stopped, it will be no great while before we shall hear of our virgin soils being exhausted. —*Queenslander.*

SETTLEMENT ON THE MOSMAN RIVER.

[FROM OUR OWN CORRESPONDENT.]

In my last I said I intended visiting the Mosman River, which I have done, making my headquarters, by invitation from the proprietor, at Hart's Coolshade plantation. This is a freehold estate, Mr. Hart being the pioneer settler of the whole district. He was one of a party who came to the river in quest of cedar in 1874 from Cooktown. After being engaged in the cedar trade for some time, he abandoned the life of a cedar-getter for that of settler. The life of a settler in those days was not an enviable one. Blacks were numerous and often very troublesome. He assures me he has been perfectly alone for six months, without seeing the face of a white man during the whole of that time.

However, things are changed now. A large and prosperous town flourishes on Island Point, which is visited by four and five large coasting steamers weekly. Instead of being surrounded by wild blacks, he has within a radius of ten miles a population of about 1,000 civilised beings. All this thanks to the Hodgkinson and Herberton fields.

I intend describing, as well as possible, the principal selections and general productions of this river. Coolshade in the first place is a selection of 160 acres, of which about 35 acres are cleared; a few acres of this only being at present under actual cultivation. The orange trees are in full bearing; citrons, limes, lemons, shaddock, mangos, thrive luxuriantly, besides mulberries grenadillas, bananas, pine-apples, and a host of others. A large number of coconut trees are also planted here, some of which are in full bearing, with large-sized luscious milky nuts. Scattered here and there through the plantation are patches of coffee plants laden with berries in all stages of advancement. This plant seems to thrive especially well in this part of Queensland, and I have no doubt that in the course of time the value of this enterprise will make itself felt. The mountain slopes of this district seem particularly adapted for its cultivation. Mr. Hart has given a small parcel of coffee berries to a southern gentleman, who takes them with him as a sample this week, so probably something of practical import may come by it. Arrowroot is also manufactured here, and finds a market in Port Douglas. The cassava plant is also cultivated, and thrives luxuriantly, as well as the ginger plant. A fine sample of cane is growing here, the Lihena, which Mr. Hart intends for plants. It differs somewhat from other varieties generally in vogue, inasmuch as fewer stalks grow to the stool, but the density is very high, a crushing of this cane returning the wonderful yield of six tons of sugar to the acre of cane.

Mr. Hart is at present engaged in an experiment with native labour. For the last week he has had eight of the Port Douglas aboriginals engaged in trashing cane, hoeing and chipping, and other plantation work. Up to the present the arrangement has been quite a success. The natives seem to be quite contented and willing to work so long as the "ki-ki" comes round regularly. The general opinion of the neighbouring settlers is that they will some fine night pack up their "duds" with something else as well and "clear."

The owner of this selection has decided on cutting up a portion of his land into allotments, and making Coolshade a town site, to be called Hartsville. I have no doubt that the venture will be a success. Up to the present no township reserve has ever been made on the Mosman, and now there is no room for one, as the only parts of the river suitable for such are all taken up. This selection and Wilson's, which is adjoining, are the only sites fit for such purpose, as they command the deep water and the junction where the machinery for the Brie Brie plantation was landed. Beyond this steamers cannot go; I mean such steamers as the Arakoon and Bee, lighters, employed by Messrs. Davidson & Co. and Messrs. Walsh & Co. respectively, of Port Douglas. Wilson's selection joins Hart's lower boundary, and is bounded both by the main river and the left-hand branch. The area of this selection is 200 acres. It is all scrub land, and commands about all the best frontage of the whole river. Some thirty acres of this are cleared and about six acres only are kept in cultivation, maize, potatoes, cane and various fruits forming the principal articles of growth. Above this again and on the left-hand branch is Brie Brie plantation, 1,280 acres, the property of Mrs. Parker. This plantation is foremost in progress on the Mosman. About 150 acres are cleared and 100 are under cane, which, for growth, cannot be excelled. The late rains have given it a tremendous spurt; some of the cane, the Meera and Rappoe, more particularly the latter, looks wonderfully vigorous. Although little more than six months planted, it is of fair density already, and promises to rival in bulk and density all other varieties. The machinery for crushing is in course of erection, the sawmill having been at work for some time. The dwelling-house for the proprietress, Mrs. Parker, is almost finished, in front of which a large vegetable and fruit garden is in course of formation. A great quantity of work has been got through here in the way of machine sheds, houses for the hands, stables, and other necessary work. About a mile of road has been made at the sole expense of the proprietress, for the purpose of bringing up the boiler and machinery from the junction. Mr. Brown, the manager, informed me that he intends crushing about July.

Adjoining Brie Brie up into the Mosman Valley is Fairymount, the selection of Mr. Pringle. The house of this gentleman, to which the name Fairymount most particularly applies, is situated on the terrace of a spur running upwards to a mass of ranges known as the Heights of Victory. The scenery from the house is extremely pretty, but when the hill is ascended still higher the view is really enchanting. Through a break of hilly coast country the sea bursts upon

the view, with the low Woody Islands and lighthouse lying upon the bosom of the water like little gardens floating on the waves. Then looking northwards the bulky form of Mount Alexandra looms in the distance, and lying over towards it, like the Leaning Tower of Pisa, is old Peter Bolt, looking smaller through the distance than his little brother. Still nearer the gaze rests upon the sombre-looking heights of Dagmar, and then turning to the southward, over the Valley of the Mosman, may be seen away in the distance the very tip-top of the big Black Mountain. The Fairymount selection is all scrub, a strip of which, about 50 acres, is cleared down to the river bank. A small patch of cane is grown here which will be planted out as soon as the boys arrive; they are expected by Mr. Pringle next steamer. Following still further up the Mosman Valley are N. M'Lean's 640-acre selections and others. On entering the mouth of the river from the bay the first landing is at W. Thomson's. Very little of this farm can be seen from the river, as the house is built a good way back, and the passage to and from the port is principally by the road. The name of this homestead, which is one of the oldest on the river, is Ellendale. It is principally a dairying farm. The next, and I should say the prettiest farm on this river, is Buchanan's. It is a 400-acre block, scrub, with a little ridgy country. Seen from a slight distance it looks like a fairy garden. About fifty acres are cleared and mostly cultivated. A splendid vineyard is planted on a hill, and the vines seem to do well. No fruit has as yet been got from them except on two or three vines which were a little more forward than the rest of the planting last season. As far as the fruit is concerned I anticipate a great success next season.

On the north side of the river are one or two selections with no improvements as yet; then you come to Mr. R. O. Jones's selection. This is a fine scrub property, in all nearly 1,700 acres; forty are cleared and mostly under maize and potatoes, besides a large variety of fruit trees, among which, I noticed a fine row of flat China peach trees. I was over during the time they were bearing, and although the trees are not so prolific of fruit as those down South, still the fruit is of a rich and rare flavour. The Mosman River post-office business is conducted here by Mr. Jones, who is the postmaster. The weekly mail leaves the Mosman every Thursday, and returns from Port Douglas the following morning. This is a means of great convenience to the settlers here, as Mr. Jones by the mail boat conveys passengers and cargo to and from the port. Although but fourteen miles from Port Douglas, there is only a bridle tract for the convenience of travellers. It is expected that the Daintree road will shortly be taken in hand; it will run through the centre of the Mosman settlements across Saltwater Creek to the wharf sites on the Daintree River Township Reserve. The great difficulty with the divisional board in this case as with others is the want of the "stuff."—*Queenslander*.

SORGHUM SUGAR.

BY OSCAR HOUCK, PH.G.

The different kinds of sorghum (*Sorghum saccharatum*) now under cultivation in the United States, are varieties and hybrids from two main groups; the one the Chinese sugar cane, or sorgho, or sorghe, from China and India, and the second the African sugar cane, or imphee, from the south of Africa. As varieties of the first group, we have the regular sorghum, Honduras cane, honey top, sprangle top, etc. Of the second group the most important are the Liberian imphees, white Africas, white mammoth, Iowa red top, and wolf's tail. As hybrids, the early amber is the most common, early orange and a number of others. These hybrids need, as also their names indicate, a shorter time to attain maturity, and are therefore especially adapted for the more northern range, Wisconsin, Minnesota, etc., where the season is rather short; while the countries further south, with a longer season, have the advantage that they can utilize both the early and late varieties, and thus be able to supply the mills for a longer time; besides that they also can utilize the other qualities, desirable in good cane, as much urine richness, large percentage of juice, and large stalks. A rather sandy loam is said to be the most favourable soil for its cultivation.

The first seeds of the new sugar cane were brought to America in 1854, from France, where they had been imported from China only a few years previous. Not long afterwards also seeds of the African variety found their way over here. And now sorghum is to be found cultivated almost in all parts of the United States, where the climate is favourable to its growth; and it is said that where maize will thrive sorghum also will.

Its principal use has, until lately, been confined to the mere production of syrup, as a very sweet, and, to most persons, agreeable article of this kind may be prepared by means of quite inexpensive machinery. But the production of a cheap, marketable sugar from it has, until the last three years, met with no success. Sugar has, of course, been produced from it long before this, but on account of inferior machinery and limited means it would not pay. It is also said that a fatty substance is contained in the juice of sorghum, which hindered the crystallization of the sugar, and necessitated another process than that used for the common sugar cane. The first sugar reported obtained from sorghum was made by a farmer in Wisconsin (according to Professor Carl Mohr). In 1858 J. S. Levering, a chemist of Philadelphia, received the gold medal from the United States Agricultural Society, as an acknowledgment for his successful and meritorius experiments in sugar making from sorghum (*Amer. Journ. Pharm.*, 1857, p. 182; 1858, p 105). In spite of the publication of his proces no attempt was made to utilize it. Later, through the Commissioner of the Department of Agriculture at Washington, G. W. Le Duc, a great deal was done in order to arouse the interest for it, that new experiments should be undertaken. Steward, a Pennsylvania chemist, also treated the subject, and showed at the Centennial Exhibition, in 1876, samples of sugar which he had obtained by his experiments. With still greater energy Dr. Collier, chemist of the Agricultural Department at Washington took up the work, and of the results of his thorough investigations he has given a minute account in his several reports, which has thrown much light on the subject.

At the same time Professor Swenson, of the University of Wisconsin, was occupied with investigations of the same kind, and when the United States Government, through the Agricultural Department at Washington, offered a prize of 1,200 dollars for the best method of treating sorghum cane it was awarded to him.

Some New York capitalists, after having corresponded with Professor Swenson and secured his service, determined to establish a sugar mill in some portion of the country, where the cane could be grown successfully and cheaply. The Arkansas river valley was decided upon, and in 1882 the mill was built at Hutchinson, Kansas. As an experiment some sugar was successfully made, already late, the same season. Last fall (1883) they made as an average forty barrels of sugar and about two hundred gallons of syrup a day. This was the first undertaking on a large scale, and, as it proved a success, others have followed their example, and many more are likely to follow.

The process used in the abovenamed mill I have not seen myself, but will give it as it has been described. The cane, having been examined by the chemist and found in the desirable ripe condition (when it contains most saccharose and least glucose), is cut, topped, and hauled to the mill without stripping. Arrived there it is placed on a long endless belt, which acts as an elevator to carry it to the crusher, which consists of huge iron rollers. The cane is passed through this crusher at the rate of twenty-five tons per hour. The juice, as it runs from the rollers, passes into a large tank, from which it is pumped into the defecating room. Here it is run into six defecating pans, capable of holding three tons of juice each. In these are coils of copper tubing, through which steam is passed to heat the juice. To the lukewarm juice is then added milk of lime, until slightly alkaline, in order to neutralize the acids, which are always contained in it, and to coagulate the albuminous matter present. It is then heated as rapidly as possible to the boiling point, and the steam is shut off when the thick scum, which rises to the surface, begins to swell and break. After a few minutes the juice is skimmed, and it is again heated, this time to a quite ebullition, and again skimmed. This is repeated a few times, and the result is a very clear juice, almost free from sediment.

From the defecating room the juice, containing 84 parts of water and 16 parts of sugar, passes to the evaporating pans, where it is boiled down to 54 parts of water and 16 parts of sugar, when it is called "semi-syrup." This passes into a small vacuum pan, and from there into the bone-black filters. These are six in number, and are each cylindrical in shape, 4 feet in diameter and 20 feet high. Here the syrup is decolorized and deodorized, after which it is pumped into the large vacuum pan. This is ovoid in shape, made of boiler iron, and looks like a huge retort. It is 7 feet in diameter, 9 feet high, and will hold more than 1,000 gallons. In this the semi-syrup boils at 70° C. under diminished pressure instead of 110° C. in free air. This is a great advantage, as it is a well-established fact that high heat and much exposure to the air quickens the conversion of saccharose into invert sugar. From the vacuum pan the syrup is put into large iron waggons, which hold about 240 gallons each, and in them is run into the crystallizing room. This room is kept at a temperature of 55° C., and in it the syrup is allowed to stand for several days until it crystallizes. The "melado," as the syrup at this stage is called, is then run into the mixer. This is a long bar with fingers attached, the whole revolving in an iron box. In this the melado is thoroughly mixed and made ready for the last process. From the mixer the melado is run into the centrifugals. These, four in number, are tubular vessels about three feet in length and two feet high, open above and closed below. Each is lined with fine copper sieve, a space of perhaps two or three inches intervening between the sieve and the outer wall of the centrifugal. The centrifugals are set in motion at the rate of 2,000 revolutions per minute, and the melado is run into them, falling upon a revolving disk in the centre. From this the melado is thrown with great force against the side of the vessel, striking upon the copper sieve, which is also in rapid revolution. The force of the projection throws the syrup through the sieve, while the crystallized sugar remains behind, whitening the longer it "spins," as the process is called. It is generally allowed to spin about fifteen minutes, after which the raw sugar is taken out and put into barrels, and the process is completed. Each centrifugal is capable of spinning 200 lb. of sugar in those fifteen minutes. Besides these details, the process has, of course, its secrets, which are also kept as such.

From the abovenamed factory I obtained a sample of sugar, of which I made an analysis, which shortly will be explained. In appearance the sugar looks very much like the common raw sugar of commerce. But in odour and taste it differs somewhat, as it has retained some of that peculiar sorghum flavour, which is not disagreeable, and in which place in common raw sugar is found a taste and smell of burnt sugar.

In my analysis of the sorghum sugar I found the following constituents:—

Saccharose	92·00	per cent.
Glucose	4·50	„ „
Moisture	1·50	„ „
Ash	1·10	„ „
Impurities	0·90	„ „
	100·00	

The amount of saccharose was ascertained by the use of the Wilde polariscope, which as an average showed 92°. With the same instrument I examined samples of different sugars with the following results (the strength of the solutions was 10 grams of sugar and water sufficiently to make 100 c. c.):—

White rock candy polarized	100°
Yellow rock candy polarized	93°
Best granulated sugar polarized	99°
White A sugar polarized	94°
Common raw sugar polarized	84°
Sorghum sugar (4 experiments)	90°, 92°, 93°, 92°

Common raw sugar was also subjected to analysis for comparison:—

Saccharose	84·00	per cent.
Glucose	11·80	„ „
Moisture	2·50	„ „
Ash	0·70	„ „
Impurities	1·00	„ „
	100·00	

The moisture and ash of granulated sugar were also ascertained and found to be respectively 0·55 and 0·44 per cent. This shows in reference to the moisture, that the more glucose contained in the sugar, the more moisture is absorbed. As to the sorghum sugar the comparison is very satisfactory, as it contains 8 per cent more saccharose than the common raw sugar, and only 2 per cent less than A sugar, which has gone through a refining process. This very satisfactory result is due to the improved machinery, of which the vacuum pan and the centrifugals are the most important, and without which the idea of sugar making, from sorghum, at the present sugar prices, might be given up as almost hopeless. But as it is, sorghum sugar can compete with other sugars, both in price and quality.—*American Journal of Pharmacy.*

FARM AND GARDEN PESTS.

Those theorists who are desirous of studying the so-called "laws of evolution" in conjunction with the dogma of "the survival of the fittest" might find a deal of mental pabulum in the various pests that trouble the farmer, and through him the whole human race. Apart from science—which cannot err—there are a number of visionary speculators who by their specious arguments and plausible theories seem to be desirous upon the one hand of proving that man was "evolved" from the lowest organized matter, through many stages, including the monkey, till he became the creature that he is today, and upon the other hand they argue that he is inferior to all other animals, because he his not naturally covered with wool or hair, that he must be nursed for several years when young, that he is not provided with sharp claws, teeth, horns, sting, or other defences of the "higher" animals; and last of all, that man's upright attitude is contrary to nature, and that he is more fitted for the quadripetal mode of progression. Unfortunately for their arguments, these theorists apply them only to man in the abstract—apart from their noble selves and their immediate friends. They speak as gods, and whilst criticising the whole universe, not one atom of which they have the power to create, they arrogantly declare that this portion of the work of the Creator is defective, that it is not perfect, and the other needs improvement. This is not so with the scientific enquirer; for he works out his enquiry until he has found the truth, and the further he enquires the more is he convinced of the perfection of all organized life and the marvellous adaptability of the various organs in each individual for supporting existence under varying circumstances of locality, temperature, and the like. The theory of natural selection, no doubt, has a very great deal to commend it, and there are almost infallible evidences that several of the higher forms of animal and vegetable life have been "evolved" from those of a lower state of existence; but it does not follow, because the seal is warm-blooded it is a mammal, and has the bones representing toes and legs within the portion of its body that is generally called a tail, that it is either a shark in the course of elevation into a terrestrial quadruped or another being transformed into a fish. It is well known that the seal is polygamus—the largest and strongest, taking charge of any conceivable number of females—so with the male deer—but upon the principle of natural selection, both those orders of animals ought to have developed into very large and powerful beasts and fierce and well-armed withal yet man finds little difficulty in overmastering either.

What has this to do with farm and garden pests? Directly, very little; but indirectly it has a very important bearing upon them. To man was given from the beginning full dominion over all things living upon the earth, and if he would prevail, he must persevere in exercising that supremacy. There are too many nowadays who forget or ignore this right, and whenever any farm or garden pests appear and devastate crops, weakly attribute the plague to influences or circumstances over which they have no control; and ignorantly propound or stupidly adopt theories concerning it which are as wide from the truth as the poles are asunder. This would not matter were there not such important interests at stake, and did not the persons who promulgate such mischievous ideas occupy positions which cause them to be looked to as being to some degree authorities upon such matters. Thus, two or three

members of an important Agricultural Society are often heard to declare with the utmost dogmatism that the mildew or red rust of wheat is caused by an exudation of the sap of the plant, which is caused by a stoppage of the upward flow, through the hot weather partially ripening or drying the stem, the sap then combining with the oxygen of the atmosphere and becoming rusty, in the same way as iron. Now, any one who examines the so-called rust with a microscope can see that it is the completion of a fungoid growth, and everyone who can read should know that its history has been published time after time during the past 100 years. The most rudimentary knowledge of chemistry should teach them that oxides of vegetables do not exist, and they must have a magnified idea of the pneumatic power of the roots of the wheat plant, if they think that they are capable of splitting straws.

"What does it matter, whether it is a fungus or a bursting out of a sap," says one, "the effect is the same—the farmer loses a portion or all of his crops through its ravages." But it is a matter of the very highest importance that the true nature of this as of all other farm and garden pests should be known to every cultivator—so that he may carry his enquiries in the proper direction. He or they may possibly find that there is a predisposing cause for any particular pest, or that there is some practice that can be adopted for nullifying its injuries. Instances of this fact are quite common. Thus, in sheep we have the footrot, which is the effect of a fungus, and the scab which is caused by an acarus or subcutaneous louse. At one time people did not know the origin of these diseases, and suffered great losses; but careful enquiry discovered the causes, and further research revealed the remedy—the first is curable most readily and cheaply by paring away the affected part and treatment with carbolic acid and sulphur, whilst the scab "insect"—it is really not an insect, but an acarus—is destroyed by the use of various dips, such as tobacco-water, sulphur, carbolic acid, &c.; the fungus affecting wheat, and known to farmers as smut, can be killed by dipping the seed in a solution of sulphate of copper or other solutions that are not so cheap or so certain—because the spores of this kind of fungoid parasite are sown along with the wheat and grow up with the plant, but the spores of the Puccinia graminis, or Uredo vera, or by whatever other name it may be known in its various developmental stages, do not attack the wheat plant virulently until the grain begins to fill. Until then, it may exist in a comparatively harmless form either upon the leaves of the plant or upon adjoining vegetation, such as barley, grass, or other weeds—in European countries the Berberis is charged with being the prolific host upon which Æcidium is produced, the spores of which attacking wheat become Uredo vexa or Puccinia graminis. This discovery resulted in the removal of all barberry bushes from the vicinity of wheat fields with markedly good results. But there are other hosts upon which the red rust lives, and it must be discovered which they are, so that they too may be destroyed. It is quite useless to apply any dip or dressing to the seed wheat to prevent red rust, because its nature is quite different from that of the bunt or smut—it would have no more effect in preventing the attacks of ret rust than it would have in preventing trespass of pigs or other animals. So far as enquiries have been conducted, it has been found that a close, warm, moist and calm state of the atmosphere at the time of the wheat plant is forming its seeds is most favourable to the rapid propagation of red rust, and it is known that this fungus feeds upon the nitrogenous juices of the plant, resulting in an insufficient nutrition of the wheat, which ripens without being properly filled up—or being "shrivelled," as it is termed. Intelligent farmers are by no means convinced that this cannot be vanquished, and it is suggested that the preceding host-plants can be discovered and perhaps destroyed; and that a better state of ventilation amongst the crops through drilling the seed in, as well as a more perfect tilling of the soil, and more liberal nutrition of the plants might prove beneficial. It is also hoped that an earlier maturing variety of wheat may by obtained or produced by selection, or that some variete may be found that will not be so easily injured by the fungus.

Takeall, again, is a pest the origin of which is not yet thoroughly understood, but it is recognised as a species of fungus or perhaps bacilli living upon the roots of plants. How it is propagated, or by what means it finds its way into our fields, has yet to be discovered, as well as the methods for combating its ravages.

Something more than a very strong suspicion is entertained that a good many insect and perhaps some fungoid pests are carted on to the fields in England and elsewhere in the farmyard manure. It is more likely to be proved or otherwise by the English farmers than the Australian, but our market gardeners and fruit growers ought to direct some attention to the matter, because they are more conversant with the use of manures than many of our farmers. After the first heat of fermentation is over in the manure, a great variety of insects and fungi take possession of the heaps, and their ova and spores, along with the seeds of plants that are flying about, may be carried on to the ground. All this could be prevented if it were possible to bury the manure before fermentation, in which case its value as a fertilizer would be much enhanced, since the whole of its volatile portion would be absorbed by the soil.

For every evil to which farmers and gardens are subject there is a remedy, but before the remedy can be applied, the nature of the evil must be ascertained. The farmers and gardeners can help themselves very materially by carefully observing when the attack commences upon their plants or animals, what are the conditions preceding and following the attack, special circumstances attending it, and any other particulars. Nothing is too trivial to be noted, but the notes must be made carefully. Surmise, or mere assertion without proof does more harm than good. For instance, during a late discussion upon takeall, one person said it was the effect of salt in the soil, because he had found a mineral which looked like salt in the same field; another said it was the effect of three species of insects, neither of which probably feeds upon plants, one such as is found near the bung of a vinegar cask, another which is found under dung, and the third an insect with a pointed tail, which insects destroyed all the roots of the plants, a third stated correctly that he had found the roots of the wheat and other plants whole, but covered with a kind of blue mould.

For some time past our horticulturists have been troubled with a multitude of pests, both insect and fungoid, and their variety seems to be ever increasing. Only within the last few days a hive of Ligurian bees was brought over from Queensland, which the importer asserted was "full of gallery moths and larvæ," and as he did not destroy them, it is most probable that our bee-keepers will be troubled. Careful observation of unknown pests, and the application of discovered remedies for those with which we are acquainted, will enable us in time to fight these various pests, whether plainly visible or only microscopic. Those who believe in the "survival of the fittest" theory may neglect these persistent parasite pests, which are so prolific and retentive of life under the most adverse circumstances, but the man who believes in the nobility of his own species, and the dominion given him over all things, will not begin to go upon all fours until he has completely satisfied himself that he is inferior in nature and organisation to the aphis and mealy bug, or the mushroom and toadstool.—*Adelaide Observer.*

A VISIT TO THE OIL AND FIBRE WORKS AT PLN. "FORTITUDE."

BY THE HON. B. HOWELL JONES.

My curiosity was aroused by the samples of coconut fibre which were given to me by Mr. Mastard, and which I had the honour of laying on the table at a meeting of this Society, on 10th May, 1883. I therefore determined to take the first opportunity of visiting the estate on which these were made. Consequently, on the 17th of May, I found myself wending my way, accompanied by Mr. Mastard, towards Mahaicony, in which district Plantation *Fortitude* is situated. No sooner had we arrived on the creek road, which has recently been put in order, than I found I was indeed in the land of coconuts. Sugar was nowhere, and King Coconut reigned in his stead. Wherever one looked, coconuts in all stages of growth surrounded the observer. And a pretty sight it is to see

the long avenues of palm trees casting a refreshing and inviting shade from the heat and glare of the tropical sun. Our first resting place was at Pln. *Sophia's Hope*, the residence of Mr. Barlow, where we were most hospitably entertained at breakfast. Mr. Barlow is indeed a splendid specimen of a colonist. Forced on account of ill-health to leave the hills and dales of beautiful Devon, he joined his brother, who was already a planter out here, and for over fifty years has made this the land of his adoption; and during the last thirty-five years has never left its shores; over eighty years old, hale and hearty, a living denial of the unhealthiness of the colony; and surely if our Honoured President merits the title of "Sugar King," Mr. Barlow may rightly be called "King Coconut." But I am digressing from my subject. After breakfast and a chat on nuts and things pertaining, we started for Plantation *Fortitude*, arriving at which we were kindly received by Mr. Smith, the owner, who immediately proposed visiting the works.

No sooner had we entered the yard than we saw piles of nuts; and it is not until a tyro, like myself, sees masses of nuts together like this, that he understands what a vast difference there is in nuts. Here we saw large, bright, reddish-brown, even-sized looking nuts which we were told came from such an estate, others dirty, brown, undersized, and shrivelled, showing care had not been taken with the estate on which they grew, tell-tales of dirty trees or drainage unattended to; but Mr. Smith makes use of them to keep his machinery employed, and all is grist that comes to his mill at present. As you enter the machine shed, you soon discover that the manufactory is divided into two distinct operations, the Oil Department, and the Fibre, the motive power for both being a 14 horse power Robey Patent Engine, this being stationary, and placed under the boiler, working with a pressure of 60 lb. the square inch.

The nuts are first divested of their fibrous covering, by manual labour, in the yard, 60 cts. per 1,000 being the price paid for this work, which consists simply of splitting the husk on the sharp edge of a hoe fixed in the ground, no better method at present being discovered. The husks are then sent to the fibre department and the hard nut, the fortune of which we intend first to follow, being broken up by a hammer, is then placed on long trays mounted on wheels, running in and out of a shed, so as to avoid danger of getting wet, should a shower of rain fall, whilst the sun's action is shrivelling the kernel, allowing it to come away easily from the hard shell. This is soon accomplished and children are employed in separating one from the other. The kernels, which at this stage are called Copra, are sent away to the store room, and the shells to be burnt to raise steam in the boiler. The copra is then placed under the crushing mill, worked from a shaft driven by a pulley, on the fly-wheel shaft of the engine, as indeed are all the machines in this department. The crushing mill consists of two large millstone wheels revolving round a large iron saucer or pan and also round their own centres; it is to all appearance like a large mortar mixer, so commonly seen in England, only in that case the saucer moves round, whilst in this the saucer is stationary and the stones revolve. The outer edges of these stones are set in such a way that each one delivers to the other the mass it has just crushed; in this way the whole is reduced to a fine powder. A door at the bottom of the saucer is now opened, a scraper, revolving with the stones, gathers the materials together and pushes it through the opening into a shallow tray ready to receive it. It is now to all appearance like damp brown saw-dust and is ready for placing in the steam-kettle, which has a stirrer revolving inside which keeps the mass moving until the temperature is raised to 120° F. A sliding door is then opened, and the mass, which has assumed an oily appearance is run into coarse cloth bags; these are put between wooden envelopes lined with tin, and placed on the iron trays of the hydraulic press. The hydraulic pumps working in oil, which are self-acting, are then set to work, the first and biggest pump quickly raising the pressure, which when it rises to a certain point is taken up by the smaller pump until a pressure of $1\frac{3}{4}$ tons to the square inch is reached. Long before this point is arrived at, the oil is seen bursting out from the bags, flowing from tray to tray, until it finally falls into a tank, from which it is pumped into the oil store. This consists of a receiving tank, a settling tank, and the pure oil, or shipping tank, arrangements being made for drawing from one to the other.

We now return to the hydraulic press from which the pressure has been taken off and the envelopes removed; the bags are now perfectly flat, and it is with difficulty they are taken off from the hard cake formed inside. This is now like oil-cake made from linseed, but is lighter in colour. Sometimes these cakes are again broken up under the mill and are squeezed a second time, or are mixed with the copra to prevent the mass under the stones from becoming too oily, and after the second pressure the cakes are fit for food. The broken cakes are ground up into powder and form a fine food for poultry, most of it being sold on the spot at 72 cts. per 100 lb., or is used for mixing with fresh copra; in this way little or nothing is wasted.

One action of the pair of presses will crush the copra from 400 nuts and yield per day 130 to 140 gallons of oil, and the filter bags used will work up 100,000 nuts before wearing out.

We then turned our attention to the husks, which are first placed in a crushing mill, worked by a belt from the fly-wheel, as are all the machines in this portion of the factory, and which consists of two deeply grooved rollers which flatten out and break up the outer silicate covering. They are then placed on trucks and wheeled to the ponds placed at the side of the tramway, where they remain soaking in water for at least a week, but generally for a much longer period, until the outer cuticle has to some extent rotted and become soft. They are then taken back to the factory and the process of extracting the fibre by the teazing machines commences.

The husk, being held in the hand, passes between two small rollers about $1\frac{1}{2}$ inches in diameter, close to which a large wheel, with its periphery covered with small teeth, revolves with great speed, which, as soon as the husk touches it, tears the refuse from the fibre and in a few seconds leaves the fibres still somewhat dirty but separated from each other. Then it is withdrawn and the portion of the husk previously held in the hand is submitted to the same process, leaving a bunch of comparatively clean fibres. The refuse from these machines goes to make what is known as "No. 2 mat fibre." The fibre just acted upon, which I have stated is only comparatively clean, is again submitted to a second process in another teazing machine kept clean for this purpose, the result being a clean sample. The refuse from this second operation goes to form what is called "No. 1 mat fibre." Mr. Smith has three of these teazing machines at work; but he finds they are not sufficient for his wants, and he has three more, on their way from England.

The fibre is tied up into small bundles, a number of these being placed together and placed under an hydraulic press forming a bale 2 feet × 2 feet × 3 feet weighing about 200 lb. The refuse from the teazing machine is again passed into a cleaning machine, consisting of a wire cylinder about 8 feet long, slowly revolving in the opposite direction to a shaft inside carrying teeth which shake out the dust from the fibres, carrying it at the same time forward and discharging it clean at the other end. This machine is most simple and effective. Of course the 1st and 2nd mat fibres are passed through separately and are packed by themselves, in bales similar in size to the brush fibre, but only weighing 120 to 130 lb. But before packing, all the fibres are exposed to the sun, for drying, and are exposed on wheeled trays running on a tramway similar to those used for drying the copra.

Thus every portion of the coconut is disposed of, and is marketable with the exception of the refuse from the mat fibre cleaning machine, no use having been found for this, except for nurserymen at home, who place it as a top dressing to bedding plants and on the pots in greenhouses, and I have no doubt our Government Botanist will be able to take some of this for the Botanic Gardens, and perhaps tell us if it would be suitable as a manure in cane cultivation.

After inspecting the works we walked through the coco. This consisted, a few years ago, of some hundred trees, but Mr. Smith with his energy has now 7,000 trees in full bearing, all kept clean and in good order. He states his

average crop is 700,000 nuts, at which Mr. Mustard expressed some surprise, as he considered it high. Here and there we saw signs of the inexplicable coconut disease, not to be confounded with the attack of the beetle, and on talking over the matter, both Mr. Smith and Mr. Mustard were of opinion that it results from the planting of green nuts, which grow much more rapidly than ripe ones, and that after bearing one or two crops they seem to get exhausted and die away. This opinion is to some extent borne out by the fact that in the older walks, such as that behind Mr. Barlow's house, the trees have never suffered. I mention this, as anything that can throw light on this strange disease or lead to a clue to the mystery must be useful to those interested in this cultivation.

In this paper I have not touched on the number of persons employed on the works or the rate of wages paid, as it must be remembered the works are only in their infancy, the full power of the factory undeveloped, and the hands unskilled in the use of the machines. Under these circumstances any minute detail of this description would be unfair to Mr. Smith and misleading to the members of the Society; but I hope I have shewn what anyone with energy and push, coupled with brains such as Mr. Smith possesses, can accomplish in establishing what are now termed "small industries," and I am sure all members of the Society will wish Mr. Smith all success in his venture, and that it may be the forerunner of similar establishments in the colony.

There is one thing which struck me on my visit to Mahaicony which I do not think it is out of place to mention here, this is the answer received to my question "Who are your labourers?"—"Oh, coolies; nothing but coolies";—a warning to those who advocate small industries, that if their theories are to be successful they must look to immigration for assistance; a rebuke, to those who are constantly grudging the revenue supplying one third the present cost; and a strong point in favour of those who know that without immigration the colony would not be what it is, and that as its success at present and in the past must be attributed to immigration so in the future will this have to be continued, if we wish to see that prosperity maintained and small industries progress and flourish.—*Journal of the Royal Agricultural and Commercial Society of British Guiana.*

AGRICULTURE AND ITS PROSPECTS IN NORTHERN QUEENSLAND.

[BY OUR AGRICULTURAL REPORTER.]

The rugged hills and mountain peaks towering so loftily in all directions around Cooktown give at once so varied an appearance to the landscape, and are so suggestive of fertile valleys and permanent streams of water, that one can hardly fail to be impressed with the adaptability of the country to agricultural purposes. Such were my impressions even before I set foot ashore; and now, after a week's hard travelling, I am convinced that no better land for agricultural or horticultural purposes could be desired than can be found in this locality almost everywhere, for I have seen scarcely any that can be regarded as indifferent soil, even the poorest of it being equal to much that is now being profitably tilled near flourishing centres of population. When the now "resurrected Cooktown," as the worthy mayor terms it, owing to the opening prospect afforded by the railway, begins growing into a thriving city with a teeming population, it will be realised that there is plenty of land on all sides capable of growing everything that a tropical climate can produce; and the many permanent streams will furnish abundance of water for irrigation purposes—a matter of no small importance in a climate like that of Queensland.

Around the port, in the immediate vicinity of Cooktown, the country is of granitic formation, the hills being a base of granite boulders, and the soil a coarse sand of the same material decomposed. As granite is known to abound in potash, this will better suit vegetation than would at first sight appear. The country around Stanthorpe, at the southern extremity of the colony, is the same, and there grapes and potatoes—potash plants—thrive exceedingly well. But the climate of Cooktown is not favourable to the growth of either of these products. In my opinion the grape will prove a complete failure; potatoes may prove a success during the winter months if properly treated; but these are matters of detail into which I cannot enter particularly in the present article. A couple of miles on the road the country alters, and changes in the formation are very frequent as you journey away from the coast in any direction.

About two miles from Cooktown by the one outlet, the road to the Palmer and other places, granitic formation ceases. The country then becomes rough and broken, and the soil varied, some of the hills being clothed with scrub, dense and beautiful, the soil being chocolate in colour, and evidently of a volcanic origin, and the open country very well grassed, all of it being well watered. There can be no question that the country on the Endeavour and Palmer, and also on the M'Ivor and Bizante, is a perfect paradise for the botanist, and that many plants unknown to science remain to be discovered by the intelligent and observant collector. It came to my knowledge that a tuberous-rooted vine, apparently allied to a plant of the *vitis* family recently discovered in the Guinea coast of Africa and Cochin China, is very abundant everywhere here. I had the satisfaction of seeing the plant wherever I went, and of tasting the fruit, some of which is of a pleasant vinous flavour with rather large seeds. The fruit is purple when ripe, and varies in size from that of a black current to that of a medium-sized grape; and the bunches vary from two or three berries to an occasional one weighing from ½ lb. to 2 lb. or 3 lb. I was told. I saw bunches with about two dozen fruit on which were of different sizes; and I could see that the flavour and size of the fruit varied according to the depth and character of the soil in which the vine grew. In some instances there were distinct traces of pungency in the flavour, which left a peculiar biting sensation upon the tongue and palate after eating them. In others there was a trace of bitterness and no pungency; and sometimes the seeds were small and juice plentiful, while in others the seeds preponderated, and there was less to enjoy. The fruit is liked by most people, and is evidently susceptible of improvement by cultivation. Having never heard of this plant before, I have thought it advisable to bring it under notice thus, as it may suggest a good substitute for the grape of more temperate climes which cannot be grown to advantage in Northern Queensland unless in the high table-lands of the interior.

* * *

Great stretches of flat land we crossed which could easily be converted into rice fields, and without much cost be abundantly irrigated. Rice thrives admirably in all this region, growing in many instances 5 ft. high and yielding an abundance of excellent grain. Mountain or upland rice is the variety grown, but even this is found to answer best when irrigated. Cooktown ought before long to become the granary for rice in Australia, and it is extremely probable that rice culture will eventually be the staple of the agriculture in the Cooktown district. This probability appears all the stronger on account of the facilities for irrigation which exist in almost every direction. The future of the district is quite assured because of the quantity of rich land awaiting the advent of capital and enterprise to develop it, and in combination therewith the wealth of water available for irrigation purpoes. As a practical agriculturist of much colonial experience, it would take but little to induce me to try my fortune in this favoured locality.

* * *

The Endeavour is a grand river—not for its size, for it is not a navigable stream for any distance, but for the steady flow of good water always in it. Its value consists in the large amount of water always available therein for irrigation purposes; and if this is not turned to good account before many years, I shall be very much mistaken.

* * *

Mr. Webb has had a varied experience in cultivation on his selection, and has followed it with great persistency and intelligence for many years and with a fair amount of success. Rice and maize have apparently satisfied him best, for he has had meagre encouragement in connection with sugar planting. I do not make these remarks with any wish or intention of disparaging the sugar industry in the North; far from it; but simply to bring out in bold relief the difficulties with which it has to contend in these remote centres. Labour has been too highly rated for agricultural purposes to allow anything like a fair margin for remuneration, except

for very high-priced articles, such as maize for local consumption and a few other things suitable for fodder. Throughout the cooler months of the year maize grows and yields well, as much as 50 bushels per acre having been garnered, but it is not so thrifty or satisfactory during the summer. This points to the necessity for obtaining water for irrigation and using the cooler portion of the year as the growing season. As the winter and spring months are almost invariably dry, growth is only possible with irrigation. Rice is another commodity which succeeds admirably wherever tried on this river. Unfortunately for Mr. Webb the bulk of his cultivated land had been swept away by the flood, the crops with the soil having been carried away together. On account of this I am not able to say much from personal observation as to the carrying capacity of the soil on this farm, but what I saw elsewhere convinced me of the correctness of all Mr. Webb told me. On an adjoining selection, owned by a Mr. M'Nicol, I saw a vigorous standing crop of rice looking its best and promising to give very satisfactory returns. Mr. Webb's experiments have been extended largely to fruit of all kinds, and he has learned that grapes and peaches are almost useless for the climate—more particularly the former. I was quite prepared to see that the grape vine was a failure so far as bearing was concerned, but I expected that it would make wood freely, which, however, would never ripen. But experience proves that they will not make wood; some vines in this garden five years planted being actually smaller and weaker than plants one year old from the cuttings in more southern latitudes. The orange is only a fair success, but if its cultivation be followed up experimentally and with intelligence there is good reason to hope it will eventually prove more satisfactory. There is abundance of soil well suited for the orange—rich scrub land full of organic matter—and there is plenty of water to allow of irrigation, and the orange is a tree which must always have moisture to do well. The mango, pineapple, banana, and papaw are everywhere at home here, and speak for themselves as to the adaptability of the soil and climate for their production. Cooktown, or some other suitable locality in Northern Queensland, should be made use of as a nursery for tropical fruits and other vegetable products; for, notwithstanding the fair amount of success attained through the efforts of the Acclimatisation Society working from Brisbane as a centre, those efforts have been to a great extent nullified by the very large percentage of loss in the plants transmitted by steamer from the metropolis. Nor can these losses be altogether avoided by any amount of care taken in transit, and the only natural remedy for this is the establishment of a nursery for tropical products at some suitable and central northern town. The mangosteen, durion, breadfruit, custard apple in varieties, cacao, Liberian coffee, cinchona, nutmeg, cinnamon, allspice, and many other spices and economic plants are well adapted for the district, and probably for much of Northern Queensland; but, until a nursery is established for them in a climate that suits them, such products stand a very poor chance of diffusion. If the interests of the North are considered worthy of attention by the powers that be, no time will be lost in attending to this matter, and the sooner it is taken in hand the better for the colony at large.

* * *

It was here that I first became aware of the existence of the tuberous-rooted vine mentioned above. I was telling Mr. Webb that the tuberous-rooted vine of Cochin-China and Guinea, now under trial in California and elsewhere, and which Mr. Pink, of the Botanic Gardens, Brisbane, was endeavouring to introduce, was the only chance for Northern Queenslanders in the matter of vine culture, when he told me of this vine, which I have made an object of special inquiry ever since.

* * *

I saw at Mr. Webb's a sample of coal gathered from the outcrop of a seam found within a few miles of his residence, and only some four miles from the projected railway line. This discovery is another very important and promising one for the port. Vessels trading with India and China are frequently compelled to steam as far south as Newcastle to obtain a supply of coal, and if they could procure it in Cooktown that port must be greatly benefited. But while I saw abundant proof of the stability and future prosperity of Cooktown and its environs, nothing impressed me more forcibly than the promise I saw in the latent agricultural wealth of the district. Whether sugar is ever taken in hand or not as an agricultural product, the agricultural resources of the district are prospectively great, and second to none in the colony; all that is required is capital and labour to develop it. At the present time capitalists are intimidated by the aspects of the labour question. Tropical cultivation is all that the climate of the North is suitable for, and the land is better adapted for cultivation than for any other purpose; and all tropical products have hitherto been the result of black labour. Whether their production by white labour is practicable or not remains to be proved. The prevailing opinion in this district is that it is not. Labour is at present too highly rated, and withal too unreliable, to warrant the outlay of capital on any agricultural industry worthy of the name. And there is no possible agriculture in the North within reach of Europeans without capital. In good seasons land within the tropics could be used to better purpose than in the raising of maize and potatoes, for which the southern colonies are by nature so much better fitted, and with which even in these things they would seldom successfully compete; but for tropical products these lands are worthy of cultivation under favourable circumstances, such as are altogether wanting.

Leaving the hospitable roof of Mr. Webb on the morning of the 6th April, we started at an early hour *en route* for the M'Ivor, intending to reach there that evening. Our course lay through country much of which had been alienated, the remainder being open for selection. The distance we had to traverse was about forty miles; journeying proved very wearisome both for man and beast, for the country was everywhere more or less rotten, and for some distance the horses had to travel through streams of water. Selection after selection untouched by the plough, but well adapted for cropping with rice or maize, and which would be comparatively easy to irrigate, was passed through. Running streams of water, marked in their course by Alexandra palms and scrub timber of various kinds, were very frequently met with, and to anyone at all accustomed to the country these streams were at once suggestive of permanence. On inquiry my companion informed me that most of them were perennial. All that is necessary in many cases to irrigate *ad libitum* is the cutting of a race to lead the water where required. Nature has also been fairly bountiful in the matter of the soil, for a deep fertile loam, mostly chocolate and friable, often almost black and sandy, and generally basaltic or volcanic in its origin, is almost universal in these localities, and one selection particularly, pointed out to me, called Glenwathen, had been chosen by its proprietors—Messrs. Webb & Co.—on account of these great natural advantages. Little or nothing had been tried upon this land in the way of cultivation, but as a preliminary to such work a wallaby-proof fence was in course of erection. Patches of rich scrub land line the creeks mentioned, the remainder being open forest lightly timbered with bloodwood, Moreton Bay ash, and other small timbers, so that the cost of clearing would not be a very heavy item; but all these forest lands must be commenced upon with the plough, so that thorough clearing and not the make-shift style generally practised, and successfully so in scrub lands, is indispensable.

Immediately adjoining Glenwathen is a selection owned by Mr. Baker, of the Great Northern Hotel, Cooktown, and at the time of my visit a very snug and commodious slab hut had been completed upon it, and a few acres of maize which had been planted looked exceedingly well. The winter in that locality suits Indian corn well, and rice can be grown at any season if there is moisture enough to start it. Speaking of starting it, the rice plant seems to have almost as many lives as the proverbial cat, and, as a rule, three crops are the result of one sowing; the worst crop of the three being the first. Passing this selection the country continues to be mostly good but very variable, sometimes light and sandy, but still fertile, and at others strong and loamy, fit for any crop the climate could perfect. But a great drawback to the profitable settlement of this portion of the country is its inaccessibility to market. It is any or all of it eminently adapted for carrying stock, but very much of it would be thrown away if put to such a purpose exclusively.

Much of the journey after passing these selected lands was over sandstone ridges running pretty high, and forming the watershed of the Endeavour River and its tributaries on the one side, and the Normanby River on the other. Pressing on, the country remains much the same, with little variations, until the watershed of the M'Ivor is entered upon. In some portions the hills are of a stratified sandstone and slate formation, and show in many places a depth of wash suggestive to the gold miner of auriferous deposits; but, although prospecting has been carried on to some extent everywhere, there are no signs to show that payable gold has been struck. As soon as the watershed of the M'Ivor is reached, and the road takes a downward trend, a very marked difference in the soil and the general appearance of the country is noticeable. The hills are clothed with excellent grasses which reached almost up to the horses' bellies, and some of the country is lightly timbered with poplar gum and has the appearance of a pretty park; the ground gently rolling and in the prime of its verdure making a very pleasing picture. Worse land than the poorest of this is profitably cultivated near centres of population everywhere; and when markets open to the enterprise and industry of our colonists, these lands may be expected to contribute their quota towards increasing the wealth and prosperity of the community. At present they are mostly unutilised, although to a very great extent selected.

Passing onwards to the open plains of the M'Ivor, a stretch of country meets the eye which involuntarily calls forth exclamations of surprise and rapture. The grasses and herbage are within one's reach on horseback, and come better under inspection there than if on foot; and the miles upon miles of almost treeless country that stretches out before one, with the courses of flowing rivers marked by a broad belt of palms and scrub timber, make up a very pleasing picture. In the distance on every side mountain ridges tower aloft some thousands of feet clothed with verdure to their summit, and every here and there these heights assume weird and fantastic forms which charm the eye by the variety they furnish to the scene. Under foot the soil is a red dust like fine ashes passed through a hair sieve, and the luxuriance of the native grasses and herbage cause the one opinion to be formed by all, that such country must be second to none anywhere for agricultural purposes. As proof that these rolling downs are naturally well watered, springs are everywhere to be seen bursting out of the hillsides. At the time of my journeying this was the case, and, although these volcanic hills or downs are not rotten, the volumes of water with which they are surcharged makes them exceedingly difficult of getting about upon. As my destination was the selection of Mr. Mader, who owned 1,280 acres in the heart of this district, we made our way direct for his homestead, being very weary of our prolonged ride. To reach it we had to cross the M'Ivor, and a grand stream of water it was; and the strength of its current was sufficient to make one wish oneself safely across. We were fortunate in overtaking the mailman, who piloted us over. A mile or so further and we alighted at our destination, and were soon discussing the mysteries of salt junk and damper over a pannikin of tea, refreshments which went down with us exceedingly well, seeing that we had tasted nothing since about 7 a.m. save water from some of the running brooks. We were very hospitably entertained by Mr. Mader, who gave us a hearty welcome, and I made the most of my visit of my reconnoitring. On this farm of 1,280 acres some 45 are cultivated and under crop, and the results were certainly surprising; but I regret to say that this surprise was not of a pleasant nature. Having heard the M'Ivor country spoken of by everybody as something grand and unequalled, it would not have astonished me had I found cultivated plots a perfect wonder of fertility. Results presented were not, however, at all up to expectation. A large field of maize which I saw was anything but strong, healthy, or vigorous. The seed had been sown just before the flood rains fell, and germinated well, but had made no headway, and looked more like a failure than otherwise. This is partly to be accounted for by the excessive rains that fell upon it; but, as the soil is naturally well drained and very porous, the deficiency cannot with justice be charged upon the rain altogether. Sugar-cane planted alongside of it was likewise weak and spindly, having more the appearance of grass than what it was. This, again, was not a natural result of the excessive rains that had fallen. I must confess that my observations greatly disappointed me as to the agricultural prospects of this naturally favoured locality. Rice planted in this 45-acre paddock was little if at all better. Bananas, pine-apples, papaws, mangoes, limes, oranges, coffee, and some other fruits were fairly thrifty; but I have seen greater thriftiness in the same plants elsewhere in my present ramblings. Very disheartening all this to those enterprising enough to settle on such lands, situated so disadvantageously under present circumstances with reference to the markets, and so isolated from communion and intercourse with the world at large! It struck me forcibly that, notwithstanding the rank growth of the native grasses and herbage generally, the soil was wanting in some of the most important fertilising elements, and, as far as my observations enabled me to conjecture the probable deficiency, I said it was potash and nitrogen, and I recommended bone dust as a fertiliser likely to suit the locality. Before leaving the M'Ivor I saw a small trial patch of cane which had been manured with burnt bones, and this was a tolerable success side by side with a comparative failure circumstanced similarly in every other particular. I was pleased to see this, as it bore me out in my previous conjecture. I noticed considerable variety in the texture and quality of the soil upon this river, but wherever any trial had been made of open forest country the results were very similar to those described above. The lack of humus is evidently one cause of these comparative failures. This is clearly shown by the cultivated plots in cleared scrub land on the river banks. At the Sonata farm, on the Morgan, the northern branch of the M'Ivor, owned by a Mr. Curle, I saw cane and maize growing in land formerly covered with scrub, and which had been cut and cleared in the ordinary way, and everything hoed in, looking much stronger and better than any other in the locality. On this farm oats are on trial; but unless I am greatly mistaken the grass *setaria Germanica* will be found to suit the climate better. It is doubtful whether any season of the year will suit for the healthy growth of the cereals of temperate climes in tropical Queensland; and, from what I have seen, I feel certain that lucerne cannot be grown to advantage so far north. Téosinte, sorghum, imphee, and some of the best of the millets, including the grass abovementioned, will suit the climate best for fodder purposes. Wherever cane has been tried on the lowlands near the rivers Morgan and M'Ivor it has succeeded, and all such land is rich in humus, and was originally covered with scrub.

My impressions of the M'Ivor country as I turned away from it were different to those I had formed concerning it as I set foot on it. Still, although in a large measure disappointed, it occurs to me that under efficient management and thorough and deep cultivation, these open plains may be turned to good account yet. It will prove ruinous to the soil there to adopt the usual practice and burn off the native grasses and herbage before breaking up the land. To realise a fair success every effort must be made to increase the amount of organic matter in the soil, as in that important particular it is manifestly lacking. All the northern scrub lands are rich in humus, and such are everywhere carrying good crops of corn and cane, even under all the retarding circumstances of an excessive rainfall. It follows therefore, as certainly as the night the day, that burning off waste vegetable matter of any kind, in this locality in particular, must prove ruinous. I would suggest to M'Ivor planters a probable and cheap remedy for the existing and proved deficiency in the fertility of their soil. Cut, dry, and burn all the mangroves in the vicinity, and convey the ashes on to the land, dressing it with the same at the rate of from two to five bushels to the acre, and note the result. The ashes of the mangrove are rich in potash, and I feel almost certain that this element is very much wanting in the soil there, as well as nitrogen. Decayed vegetable matter will help it with nitrogen, and wood ashes, especially of the mangrove, with potash and lime, and if then it does not yield better I shall be surprised. Lime alone I cannot think will help the M'Ivor soil in the least. I almost felt regret at having seen the M'Ivor, because it compels me to express myself as above. Still, if there are defects the sooner

they are discovered and attempts made to remove them the better it will be for those who have taken up land there.

After visiting almost every patch of cultivation on this river, I turned Cooktownwards. My companion and I took another direction in returning, to visit some other selections on the Endeavour, and we pulled up first of all at Bustard Park, owned by a Mr. Williams, and situated about twenty-five miles from Cooktown. In all my rambles I have no recollection of seeing a prettier piece of natural scenery than here burst upon my view. The selection consists of a number of well-grassed plains and considerably elevated bald hills, with well-wooded heights on every side, and permanent streams of pure spring water meandering in various directions through the property. I heard the remark made that it was the prettiest place in Northern Queensland, and certainly I have no inclination to call this in question. One could not, however, but be struck with the extreme unfitness of the residence for its surroundings. A lordly mansion would grace the scene, and would be in perfect harmony with the choice and attractive spot. But there are other things besides the general appearance which add value to the spot. The soil is of excellent quality, and when I mention that maize crops to the extent of fifty bushels to the acre are frequently taken therefrom in a fair season, that fact will speak for itself. But the present proprietor is not a farmer, and has no idea of becoming one. Being engaged in the butchering business, he selected it in order to have land for cattle, and has farmed a little as a necessity for his horses and stock. Most of his land is good agricultural, and capable of carrying any crop for the maturing of which the climate is suitable, and is equally adapted for the growth of either sugar-cane or rice. From what met my eye I should say that the defects in the M'Ivor soil are not repeated here.

From this beauty spot I was piloted to Mr. Dick's selection, a few miles away; and there I saw both corn and sugar-cane as thrifty as could be desired, and promising a satisfactory yield. Fruit and coffee are Mr. Dick's fancy, and for these the soil and climate are admirably adapted, if proper cultivation be carried out. I saw Liberian and Arabian coffee doing fairly well, but not showing such progress for the time it had been planted as I expected. The reasons for these shortcomings were also manifest, but I could not attribute them to the soil. The want appeared to be experience in managing the nurslings. I saw small pot-holes being made for young coffee plants in otherwise unbroken soil under heavy standing timber, and such in my opinion is next, in the matter of expecting satisfactory results, to putting them into the fire. Growing timber monopolises every particle of moisture and fertility within the reach of its roots, and large established ones are certain to starve any young tree which has to struggle into existence in their vicinity. A short distance further I came to a selection owned by Mr. Stitt, a Cooktown butcher. There I saw a standing crop of maize looking well for a good crop, and everything to speak for the fertility of the soil and its suitability for cultivation under cotton, maize, cane, or any other tropical plant. From this point we retraced our steps and worked our way back to Cooktown, arriving there at a late hour on Wednesday, after a five days' wearisome ride over rough boggy country and strongly-running creeks and rivers. On the following Saturday I went on board the S.S. "Archer" *en route* for Cairns.

Approaching Cairns from the sea, it strikes one that a very limited area of country can be available for cultivation between the mountains and highlands. From the open roadstead one obtains a glimpse of the town, situated on low land but little above the level of the sea at high water, and apparently close at the back rise lofty mountain ranges covered with a tropical scrub. On landing, however, these impressions prove deceptive. The town is on a sandy flat covered with timber of various descriptions, and in the main street are many huge specimens of figs and magnificent trees of other kinds which are admirably suited for shade purposes, and should certainly be preserved in their integrity. The admirer of nature visiting the place for the first time naturally admires these trees, and in looking among the branches espies numerous orchids and epiphytal ferns and plants which interest him. All these northern scrubs are immensely rich in varied and pleasing novelties which charm the eye of the horticulturist and botanist, and tempt him continually onward in the way of feasting his eyes and exploring.

I landed at Cairns from the S.S. "Archer" on Easter Sunday morning. On that day of course travelling was out of the question, and, Monday being a holiday, the charter of a horse was impossible. Before the day closed, however, I found a friend in the staff-surveyor—Mr. Starkey—who kindly volunteered the loan of a horse during my stay, which I very thankfully accepted. The next morning Mr. Starkey and Mr. Hartley invited me to accompany them by boat by the Trinity Inlet, as in that way I should reach the camp where a horse for my wanderings would be obtainable. Unfortunately a soaking rain was falling while we progressed up the inlet, which militated very considerably against our enjoyment, and also spoilt the view. But I was very much struck with the capacity of this inlet as a safe and commodious harbour for a very large fleet, and it occurred to me that this fact alone would go a long way to justify the construction of a railway from Cairns to Heberton, which, I see, has been finally determined upon. Mangroves fringe the inlet everywhere, and among the branches a great variety of orchids and ferns were conspicuous. On coming to a spot where there was some appearance of open forest country we landed and refreshed ourselves with a substantial lunch, and after reconnoitering went again on board and pierced the intricacies of the stream further upwards towards the source. Soon, however, the banks began to contract so that we could not navigate it, owing to the mangroves shutting it in over head, and we reluctantly turned back and proceeded to the landing at Redbank, where we saw a large quantity of the machinery landing for the Pyramid Plantation on the Mulgrave River, some nine miles distant. After about an hour's delay here horses were brought from Mr. Starkey's camp, and we mounted to make for the quarters it would afford us for that night. The road was, like many in the North this very wet season, only just traversable. The country is open forest land, timbered with small bloodwood moderately, the top soil being poor and hungry, with a tenacious yellow clay for a subsoil. After a ride of a mile or two the camp was reached, when we dismounted and proceeded to make ourselves as comfortable as possible under the friendly covering of canvas. My friend and host for the time being was extremely kind and attentive, and the time passed merrily. The next morning I bade adieu to Mr. Starkey, and pushed on for the busy scenes of the Pyramid Plantation, some eight miles distant. But little change was noticeable in the character of the country for miles, except that the soil materially improved until it appeared to be admirably adapted for cultivation. So far as I could judge on horseback it was a friable loam of considerable depth, in places fairly strong and adapted for the growth of rice, maize cotton, and tobacco; and in others more light and sandy. When approaching the north bank of the Mulgrave the country altered into a very dense scrub, full of heavy timber in great variety, but from which most of the cedar and valuable timber trees had been taken. Wild bananas, lawyer and other vines in endless variety, the stinging tree, varieties of the wild ginger, and ferns and orchids innumerable greeted my eyes everywhere. After a mile or so of this scrub the north bank of the wide-spreading Mulgrave was reached, and a waste of loose soil and boulders had to be traversed before coming to the stream itself. The water was not much above the horse's knees and was as clear as crystal, coursing over a pebbly bed, and was a very refreshing sight. On enquiry I found that the volume of this stream seldom fell much below what it was then; an exceedingly satisfactory discovery for a Queenslander accustomed to stagnant pools and dry beds of rivers as an annual occurrence. On crossing the river the works of the Pyramid plantation came under notice. The scrub had been cleared on the south side of the river by kanakas and Chinese, and a gang of the latter was busy planting between the stumps and logs, by contract, as I passed. A little farther on the buildings for the proper working of the plantation appeared, and the scene opened out beautifully.

* * *

The Pyramid estate contains over 5,000 acres of scrub land of volcanic origin, and very rich in organic matter in

all stages of decomposition. When the plantation was started the intention was to extend operations upon it as fast as practicable, but since the supply of labour has been interfered with the proprietors have been compelled to limit their enterprise for fear of its ending in failure. So far as I could learn they regret having gone so far as they have, for prospects are anything but assuring, and but for the fact that a start had been made and orders given in the old country for machinery, a complete stoppage would have taken place. The main portion of the crop of sugar-cane on this plantation consists of Rose Bamboo and Meera. Creole is growing there, but not in large quantity; and the general opinion there and elsewhere is that the Creole and the Meera are identical. Cheribon and some other varieties, including several ribbons, are also under trial. Experienced planters say that canes are variable, and are all liable at any time to failure, so that it is always wise to have other varieties at hand and available in case of emergency. The labour now employed on the plantation consists of 35 Europeans, 81 kanakas, and 100 Chinese; and about 140 more kanakas are expected to arrive shortly. The kanakas are everywhere happy and contented, and appear to do their work as cheerfully as if not more so than any other people. The Chinese are anything but reliable, and unless very sharply overlooked they will skulk and loaf frightfully, and try in every way to take advantage of their employers. The same is the experience with Europeans in any field labour. Much of the contract work in clearing, burning off, and first planting is undertaken by the celestials, and only when thus dealt with can they be employed advantageously. The machinery for the plantation is all either landed or on the way, a vessel having been chartered to deliver it on the spot for a lump sum and to carry nothing besides. Three hundred tons of machinery is already landed, and an equal quantity is yet to arrive, which includes tramway appliances for doing the work of the plantation. The machinery is to be conveyed to its destination by means of the tramway imported, and this work alone will necessitate a large amount of labour. Manlove, Alliott, Fryer & Co., of Nottingham, are the makers of the machinery, which is equal to the manufacture of 10 tons of sugar every twelve hours. It consists of double crushing rollers, French double-bottom clarifier, filter press, triple effét, and vacuum-pan, three multitubular boilers 8 ft. in diameter by 14 ft. long, with 136 tubes each, and separately up to 115-horse power. A Godillot furnace is to be used to burn the megass as it comes green from the rollers—an appliance which is variously spoken of, but which has not been thoroughly tested in Northern Queensland. At the present time a sawmill is worked by steam, the engine being of 14-horse power (by Robey), and which works a vertical as well as several circular saws. All the timber required is cut on the ground, and the sawmill employs a considerable number of hands in many ways to keep it going. The buildings erected for labourers are all that could be desired for the purpose, being roomy, well ventillated, and evidently constructed with due consideration for the health, comfort, and well-being of those who are to occupy them. The European quarters are nearly a quarter of a mile from the kanaka house, and form quite a comfortable block of buildings. The kanaka house is built to accommodate 160 hands, and, as the "boys" will not be content without fire to sit by during evenings, provision is made to allow them to make a fire in the centre of the building upon the floor, where they can squat all round it, the smoke having a good get-away in the roof above. Foundations for the mill are in course of excavation, and concrete walls for molasses tank and other pits are now being made. The gravel and sand for the work is being brought across the river by means of a wire-rope and bucket, and preparations for the coming machinery are well forward. It is early as yet to fix a date for the erection of the machinery, but should no unforeseen delay take place, crushing is expected before the season is through. Another 400 acres of cane is to be put in ready for the following crushing. All things considered, there appears to be a fair prospect of good returns for the outlay on this plantation at no very distant date, and work is being pushed on under the management of Mr. J. B. Louridan with all the expedition and forethought possible. After enjoying the hospitality of the host and hostess, I made a start early the following morning for the Hambledon plantation, particulars concerning which will be furnished in my next.

Between the Pyramid and the Hambledon plantations the country is nearly level, and in dry weather is a good easy road to travel, the distance being about eight miles. A large portion of the land along the track is very indifferent, fit for nothing but pastoral purposes and not very good at that. The remainder is tolerably fertile and workable, but being open forest country will be long in tempting cultivators to try it, as such land is mostly costly to prepare and uncertain as to results, even when in texture and appearance exactly resembling scrub soil. The proprietors of the Hambledon plantation are Messrs. Swallow & Derham, and a visit to the spot is sufficient to satisfy anyone as to the energy and enterprise of this well-known Melbourne firm. The exact amount of land held by this company I did not ascertain, but it is considerably over 5,000 acres, mostly first-class scrub soil, well situated for working and also for attractiveness. Rising immediately behind it is a lofty range of scrub-clothed hills, or rather mountains, known as Lamb's Range, which tower up to the height of between 2,000 ft. and 3,000 ft. The land under crop was formerly called the "Blacks' Square," as the immediately adjoining patch had been utilised by the aboriginals as a trap to run cattle and horses into for use as they wanted them. A lofty range towers high above the cultivated portion of the estate towards the west and north, and anyone enjoying leisure, and well armed against the persecutions of that minute insect which causes the "scrub itch," may, in the ravines which show among these heights and in the wealth of tropical vegetation everywhere appearing, fairly revel in many of the richest of nature's botanical adornments. But I lacked the needed leisure, as on arriving at the mill I was introduced to the captain of a small steamer—the "Star of Hope"—trading between Cairns, the Johnstone and Herbert rivers, &c., and Townsville; and as my next port of call was the Johnstone, I hurriedly determined to take a passage southward in this little craft. Ascertaining that she would leave that evening I saw I had no time to lose, so I gathered the information I required, partook of an excellent lunch, and was soon afterwards in the saddle *en route* for the Hop Wah plantation, and thence to Cairns.

Although Messrs. Swallow & Derham have only been in possession of the land a little over two years, there is about 800 acres under cane, all looking well; machinery erected capable of making 10 tons of sugar in twelve hours; all the necessary buildings for the accommodation of the hands employed on the estate; and last season cane from nearly 800 acres was crushed, which resulted in a yield of sugar nearly up to 1,300 tons. Evidently no time had been lost in any way, and, in addition to the above work, a substantial tram line, four miles in length, has been constructed, leading from the mill to deep water in the Trinity Inlet, and a good wharf erected, where vessels of considerable tonnage can come up alongside and load or discharge. Labour and capital combined work wonders, and the transformation thus effected is not only creditable to the enterprise of the proprietary, but is equally so to the colony in which it is displayed. As mentioned above, when all this was planned and in course of preparation, the capitalists who were making such ventures did it on the strength of a plentiful supply of coolie labour, and the promise held forth by that fully justified the undertaking and the outlay. Now, however, the prospect is not encouraging, and there is no desire at present to push ahead as before, but simply to hold on in hopes of another and a more desirable change. The labour employed here, as elsewhere, is various. Chinese have been tried, but are found more or less wanting, and only six are at present engaged. There are, besides, 175 kanakas, and between thirty and forty Europeans. All the employés are comfortably housed and cared for, but the arrangement of the buildings is not so complete and symmetrical as could be desired, and is somewhat out of joint with the grandeur of the surroundings. The impression conveyed to the observant visitor, on surveying the scene, is that getting speedy returns was more thought of when doing all this than the idea of making it an attractive and pleasing picture. Certainly to the planter's eye the luxuriant fields of cane stretching out before him would be an unfailing source of delight, but it is always a pity to overlook the picturesque, more

especially when Nature has been so bountiful in supplying her part.

As already mentioned, the machinery is not particularly large for such an estate. Double crushing has not been hitherto attempted, but an extra set of rollers is being made by Walker & Co., Maryborough, to be erected for the next crushing. All the latest improvements, such as triple effét vacuum pan are in use, and the machinery is worked by steam generated by three boilers of 60-horse power each, and a fourth boiler is now being made by the Maryborough firm already mentioned for the next season. About 950 acres are under cane for next crushing, and the crop at present is looking as well as could be desired, being a mass of impenetrable cane more than 10 ft. high, dense enough to shut out both light and air from anyone attempting to push in among it. When I asked the opinion of one of the firm who showed me round whether he thought white labour could ever answer for field work on a sugar plantation, his immediate answer was, "Go in among the cane a little and judge for yourself." But I needed no such experience, having tried it years before in a more southern latitude, which convinced me that until the nature of the white man had undergone a considerable change, or some great pressure of circumstances, such as the inducement of high wages or the prospect of an empty purse and starvation, he would never be induced to undertake such work. There is nothing like experience to settle such questions. Those who have no experience, and never attempt to acquire it, should be more moderate in their utterances if they would be accredited with wisdom or common sense. I had almost forgotten to state that a charcoal plant from the Fives Lille Company is to be added to the machinery shortly; extra centrifugals from Mirlees, Tait & Watson; and also a Godillot furnace for burning the megass.

I have said that no effort is being made to extend operations; I was informed, however, that 950 acres of cane is to be crushed the coming season, and it is confidently anticipated that a high average density will be obtained from the crop, should the season continue good. The ratoon crop is expected to average from 8 ft. to 10 ft. of cane for the mill, and the probability is that should the labour problem be satisfactorily solved, we shall yet hear of great success being realised from the Hambledon plantation. While in conversation with the gentleman who showed me round, I was again reminded of a mystery that had greeted my ears several times before. I was told that in the adjoining scrub could be seen specimens of native ginger producing widely dissimilar fruits on the same plant. Feeling certain that a mistake had been made, I decided to take time to try and solve the mystery. Fortunately we saw the dissimilar fruits, and they were both on specimens of the *zingiberacea*, but they were distinct varieties of such, and by no means identical. Having solved the mystery we returned, and I took my departure *en route* for the Pioneer plantation.

After a lonely ride of some five or six miles on the Cairns road, sugar again came into view, and I turned aside to hurriedly inspect the workings of Hop Wah & Co. The bulk of the land under crop with cane on this plantation was originally covered with scrub, but the limited time at my disposal would not allow of my going through it, as it lay a good distance back from the road. One feature of the place is that it is worked entirely with Chinese labour, the only Europeans being the sugar-boiler and the engine-driver, Celestials being wanting in the qualifications necessary to superintend these important operations. The number of Chinese employed is about 200, including the overseers or gangers. As matter of course the labour difficulty is felt little, if at all, by this company, except that there is a general feeling of depression and uneasiness in connection with the industry. The anxiety that was shown only a short time since by Melbourne and other capitalists interested in sugar is now a thing of the past; banks refuse to advance capital to assist industry and enterprise in developing it, and a certain amount of fear is entertained that it may yet collapse. Hundreds of thousands of pounds have thus been shut out of the colony, and Europeans who would have been snapped up at good wages less than a year ago are now wandering about unable to obtain work even at greatly reduced wages. There are facts which are apparent at every turn all through the northern sugar districts, and as such they are immensely instructive. But to return to my Chinamen. This plantation is only some three miles from Cairns, and on riding through the settlement quite a village of thatched dwellings marks the place where the workmen are domiciled. Everywhere in my travels I have found that the Celestial erects his buildings of thatch—not only the roof being of this material, but also the ends and sides. Some of the larger ones are like huge barns, and are partitioned off within to accommodate a large number. Much of the thatching is done with the trash from the cane, and when anything like care and skill is bestowed upon the work it is almost a marvel of neatness, and is thoroughly wind and water proof. The amount of land owned by this company is 1,280 acres, much of it being swampy forest land, and a portion of it rich scrub. Some 400 acres is now under cane, and last season 180 acres was cut and crushed, at an average, I was assured, of 2¾ tons to the acre. So far as trials made are concerned, scrub lands yield immensely, as much as 4 tons to the acre being given as the yield. Forest land, however, will not give much over a ton. The varieties of cane grown by this company are the large yellow, black Java, Rose Bamboo, and Meera, the two latter being the principal favourites.

Without unnecessary delay I pressed on for Cairns, where I found that the "Star of Hope" would be ready for starting in an hour or two, so that I had little time to spare. Before leaving I was kindly furnished by the Sub-Collector of Customs, Mr. R. T. Hartley, with some facts and figures relating to this young industry in that port. The total quantity exported last year was 1,367 tons 5 cwt. of sugar, valued at £37,409; and 44 tons 12 cwt., valued at £1,246, had been shipped coastwise; the total for the year ending 31st March being 1,411 tons 17 cwt., valued at £38,655. This does not represent the total output of sugar from the mills in the district, as a year's supply for the place has to be added. I lacked opportunity to inspect the rich scrub lands of the Barron River, but, as I understood nothing more than the preliminaries of clearing had as yet been attended to, my anxiety to push in that direction was not great. Hurrying on board, the captain let go his moorings, and we started for the Johnstone River.—*Queenslander.*

THE following is from the report of the American Consular Agent, Lowenstein, of the province of Gras, Spain, and will be found of some interest to orange growers:—"Trees raised from the seed are more robust and live to much greater age. The oldest orange trees found in this province clearly demonstrate that the primitive trees were raised from seed. The sweet orange does not thrive well when raised from shoots, and in order to obtain a good result it is necessary to recur to tightly bandaging them so as to favour the accumulation of juices, which contribute to the acceleration of the unfolding of the underground shoots. The bitter orange is more easily cultivated. The following means have been employed and are still being used, as by the same frondose trees bearing a large quantity of fruit, and this of good quality, are obtained. Said means are these:—First a flower-pot is obtained, composed of two pieces, which can easily be fastened together either with wire or strong twine passed round them at the top and also at the bottom. Then some straight branches of about the thickness of two fingers must be selected, and if said branches are very long, they should be cut down to the length of 1½ metres; then the part that has to be placed in the centre of the flower-pots is barked all round for about 1½ in., and immediately bound up with esparto grass cording. As soon as this is done the flower-pots are put together and filled with earth and stable manure, well mixed together, and watered; after this they are watered once a week. At the end of a year the roots that have formed nearly fill the inside of the flower-pots, and then the branches at the lower exterior part of these are sawn off and the new orange trees are taken to the spot where they are to be planted. For planting there is only to cut the wire or string holding the flower-pots together, and if they are well looked after they will commence bearing fruit at the end of two years."—*Queenslander.*

YIELD, PRICES AND PROFITS OF INDIA TEA ESTATES.

The *Home and Colonial Mail* contains interesting roports of the annual meetings of three Indiau Tea Companies, viz.,

The Jhanzie Tea Association, Limited,

The Lebong Tea Company, Limited, and

The Land Mortgage Bank of India, Limited.

Regarding the first the Chairman stated that

Although the quality of the tea was better than in the previous year, it was not by any means so good as the management would like to see it, or indeed so good as it was in 1881. The cause of this laid in the unfavourable character of the weather experienced last season in Assam, the tea suffering in consequence. Another serious point to be noted was the falling-off in the outturn, which likewise was to be attributed to the adverse weather that had prevailed. These, of course, were circumstances over which the managing agents could not exercise any control. He was however, happy to be able to add that they had good ground for looking forward to obtaining tea of a better quality and a larger outturn during the current twelvemonth. The proprietors would have already seen from the report the sad news that had just come to hand concerning the death of 85 coolies from cholera, and although that number of hands had been replaced by local labor which had been supplied free of cost, a loss of five thousand rupees had fallen on the Company in consequence. That again was a matter over which it was impossible for the management to exercise any control. The expenditure on buildings and machinery had during the last three years been very heavy. Judging from the plans lying on the table of the withering house, the tea house and other departments the proprietors would he thought agree with him that the Company's buildings had been brought into a very perfect condition.

Our readers will thus see that to meteorological conditions in Assam, over which those in charge of the estates had no control, were due the impaired quality and decreased quantity of tea-yield. The present year has shown, that, even in Ceylon, those interested in tea estates must be prepared for the unfavourable effects of abnormal weather, and must, in such case, follow the good example of the Jhanzie Association Chairman who held the managers blameless. Blameless also, of course, he held them for the providential visitation of cholera, which had lessened the labour force of the estates by 85 coolies, the replacing of whom led to an extra expenditure of R5,000. This is a form of casualty to which estates in Ceylon are not likely to be subjected. There was the prospect of better tea and more of it next season, and, meantime, the estates had been supplied with a first-rate tea-house and improved machinery. As these were supplied out of revenue, our readers will see the unreasonableness of the complaints which were subsequently made regarding the amount of dividend. A new tea-house and new machinery ought properly to be changed against the capital account. Shareholders cannot have the improvements and the money (well laid out) which they cost. The Chairman proceeded to discuss the probable future of the tea enterprize after a fashion which is as interesting to us here in Ceylon as it can be to our competitors in Assam or Darjiling:—

Those present being all more or less acquainted with the subject in hand, it was unnecessary to do more than briefly mention that in his opinion that they were on the eve of considerable changes in the tea trade, and he was afraid they must look forward to somewhat lower drices if what was reported concerning the advent of new supplies from Ceylon, Java and China proved correct. The only hope lay in increased consumption, and unless that took place to some considerable extent they must prepare themselves for the receipt of lower prices for Indian tea in the future. Under these circumstances it behoved everyone connected with the industry to reduce as far as possible the cost of making tea, for it was only by placing the article on the market at a low price that its consumption could be forced. The deliveries of tea for May were larger than any ever known in this country—exceeding 6,000,000 lb. Now if that rate of consumption, could be maintained they might rely on finding a fair market for all their produce, otherwise a fall of ½d to 1d per lb. must be looked forward to.

A wise economy must be enforced, and there can be no wiser economy than that of supplying good tea-houses with the very best appliances for withering and the most perfect machinery for rolling, drying and sifting the tea. The experience of the Assam Company recently quoted by us shows that the introduction of improvements in preparation enabled them to meet and obviate the effects of a fall in price equal to 50 per cent. At this meeting the low rate per acre (370 lb.) and the heavy cost of making the tea (1s 1½d or 1s 1¾d) were subjects of complaint, but we have already noticed that a tea-house and machinery had been provided. Mr. Tye said:—

Compared with the companies mentioned, it seemed that they had made the lowest amount per acre—viz., 370 lb., against 390 lb. by the Dejoo and 395 lb. by the Borelli. The Scottish Assam, which made the same out-turn as this company—370 lb. weight per acre—showed a lower rate of cost—viz. 11d per lb. as against their 1s 1¾d. The Borelli showed a cost of 10½d and the Dejoo, 11d.

Mr. Tye, went on to say that in view of the fact that their tea had cost so much to produce, it was only natural to suppose that they would get a corresponding benefit in the price realized by the tea. The Scottish Assam costing 11d. had realized 1s 4½d as against their 1s 2d—a very serious difference. He further noted that their local cost was very excessive compared with that of other gardens—a fact that would explain probably how it was their tea cost more in Louden than that of the companies he had mentioned.

Mr. C. Hudson pointed out that in estimating the expenditure of this company, account should be taken of the exceptional cost incurred in respect of labour and also as regards buildings and machinery, all of which expenses had been charged against revenue.

Mr. Tye said the figures were yet more striking if they took the profit per acre realized from pure tea and compare it with that of other companies. The Jhanzie showed a return of £2 11s 3d, the Dejoo of £6, the Borelli of £7 17s per acre. Having regard to these figures there was he thought plenty of room for improvement in their position. At the same time it was satisfactory to observe that upon the whole a better result had been obtained this year than the year before.

Mr. Lawrie (of Alex. Lawrie & Co., Managing Agents) said that the comparison instituted by the last speaker was scarcely fair, seeing that the Dejoo garden had had an exceptionally good season, while moreover the accounts were kept in a totally different manner to that adopted by this Company. At very considerable expense this estate had been brought up to a high pitch of perfection and the cost of everything in the shape of new buildings and plant had been charged against revenue. Then as to the Borelli estate he could not speak very fully or definitely, but this much he might mention on good authority that it was one of the best and most easily managed estates in India. In view of these facts a simple comparison was scarcely fair.

Differences, such as those mentioned, of superiority of position and the mode of keeping accounts, must be allowed for in Ceylon as well as in India. It was finally resolved, at the meeting we are referring to, that

In view of the possible lower value of Indian tea, eno-

sequent upon increased supplies, no expenditure during the season 1884-85, after this date, be incurred upon new buildings or machinery without the sanction of the shareholders in general meeting.

Next comes the report of the Lebong Tea Company, one of the oldest and most successful in Darjiling. A large tract of land had been purchased for the sake of the forest on it. The Chairman said they had reason to be pleased with the prices obtained for their tea, but he felt anxious regarding the future. He stated :—

I am afraid that the opening markets have not been quite so favourable as we should have been glad to see. The increase which has of late taken place in the consumption of Indian, compared with China tea, goes to show that the quality of Indian tea is asserting itself very satisfactorily, and as Indian tea growers the great object now before us (quality being the distinctive characteristic of Indian tea) is to make the quality of this Company's teas as high as possible. To that object our Manager, Mr. Christison, has devoted his special attention and he trusts—and we sincerely echo that hope—that in the next year the quality of our tea will continue to improve. The improved prices that we obtained last year has enabled us to increase the dividend substantially, and instead of paying as we did last a 6 per cent. dividend for the twelve months we are now in a position to recommend to the shareholders the distribution of 9 per cent., 3 of which has already been paid as an interim dividend and it is now proposed to pay the remaining 6 per cent. (Hear, hear.)

Sir James Caird then went on to say :—

Then with ragard to one item in the expenditure, namely "Commission." Probably many of the gentlemen who have looked over these accounts must have been somewhat startled at seeing such an item ; and I must say it does appear in very dangerous proximity to the salaries of the directors. The fact is it represents commission that is paid to the managers, and forms a sort of percentage upon the dividend. It is of great importance to unite the interests of the managers of the different tea plantations in obtaining the very best quality that can be got, and in that way of realizing a good price for the article, and we think we have secured that end by giving a certain limited commission to those gentlemen for bringing about this satisfactory result. (Hear, hear.) On the opposite side there is an entry that appears for the first time namely, "loss by taring" —that is the loss which arises in the taring or the opening of the boxes at the docks. We are endeavouring to see whether we cannot get rid of the necessity for this taring at the docks here and be treated in the same manner as the "Heathen Chinese," who has not his chests opened.

Mr. Law:—The China tea chests are about the same weight, ours, vary ; that is the reason.

The Chairman :—That we are steadily endeavouring to correct.

The Mortgage Bank of India had a very different tale to tell : not only no profit, but a considerable addition to the balance to the bad. There had been a falling-off in crop last season, production had cost too much and a disposition was evinced to find fault with the management. The Bank owns properties in various districts, and those in Darjiling were favourably spoken of :—

It is unsatisfactory that with an increased crop and a better average price there should not be a larger amount of profit. This, however, is in some measure accounted for by the upkeep and cultivation of a larger bearing area becoming chargeable to revenue without corresponding increase in crop and by heavy but necessary expenditure on machinery and stores during the year. As stated in our last report, the attempt to open out profitable markets for Indian tea in Australia and America have been attended with but little success. We made no shipments to either of these markets, during last season, either directly or through the Calcutta Syndicate, and the results from the sale in Calcutta of the teas that we had prepared for those markets were by no means satisfactory.

Our readers will observe that a visitation of blight and red spider was traced to abnormal weather, drought prevailing in the early part of the season. In Assam, low yield and high cost were subjects of complaint. In Cachar, yield was short of estimates, and the climatic conditions were the cause. It is stated :—

This short fall is mainly attributable to the severe and long continued drought which prevailed during the early part of the season, followed by storms, and floods in May and June, and again in August, with the necessary consequences of blight and prejudice to cultivation, entailing by short out-turn a heavy cost of production.

We in Ceylon are by no means likely to suffer from weather as they do 20° further north, in regions where earthquakes and storms occur and where hail is common and destructive. It is said :—

We regret to add that in May, 1884, two heavy hailstorms again occurred at Jalingah doing damage to plant as well as to some of our buildings, and being likely to prejudice the current season's outturn.

In Sylhet also yield was short, the reasons being thus stated :—

The short fall may be accounted for by the prevalence of unfavourable weather, for although there appears to have been but little blight the leaf hardened rapidly and ceased to grow. The average sale price of the teas has been 1s 1·26d per lb., which cannot be considered satisfactory Owing to the low acreage yield the cost of production has been 11·11d per lb. Outbreaks of smallpox and cholera at Shahazpore have recently caused us much anxiety, but we are glad to say that according to our latest advices both those diseases were disappearing. At Shahazpore there is a good supply of timber, and we are now making arrangements for the manufacture of tea boxes on a large scale for general use at our gardens in the district.

At Kolabaree there was want of sufficient labour for cultivation and manufacture. The conclusion is :—

The estimated crop was 7,130 maunds or 570,400 lb. and the out-turn has been 7,175 maunds or 574,000 lb. The average sale price of the teas from the Upper Division has been 1s 4·52d per lb. whilst the teas from the Lower Division have realized an average price of 1s 7·27d per lb. The cost per lb. of the Upper Division's teas (laid down in London and taking rupee expenditure at 1s 8d) has been 10·84d per lb. and the cost of the Lower Division's teas 11·32d per lb. The season's profit from the Upper Division has been £6,431 0s 4d, and the like profit from the Lower Division £9,717 7s 3d, the aggregate being £16,148 7s 7d. The actual yield slightly exceeded the estimated quantity and but for the unfavourable weather which prevailed during part of the season and the early closure of manufacture, this excess would probably have been larger. The earlier portion of the season was very hot and dry, and up to June but little rain had fallen, the consequences being visitation of blight and red spider at some of our gardens which necessarily prejudiced the crop. The expenditure upon buildings and machinery during the year was large but both buildings and machinery are now in such good condition at most of our gardens that we may anticipate material reduction in these items in the future.

This Bank has leeway to make up, and so with a good many other Indian "concerns" on which there had been large expenditure in former times. Many planters here will have the same discrepancy in accounts, if the previous expenditure on coffee and cinchonas is counted against estates converted into tea plantations. On the other hand, the ground will be ready for planting.

The paper we are quoting from gives also a table show-

ing the results for 1883 of a dozen Indian Tea Companies. The largest paid-up capital is that of the Mortgage Bank of India, £308,468; the smallest £43,560, in the case of the Borekai Tea Company. The Bank possesses only 6,645 acres against the 7,600 of the Assam Company, but then the Assam Company got "for a song" what had cost a mint of money. The smallest acreage is 556 in the case of the Dejoo Tea Company. The capital per acre ranged from £25 to the enormous sum of £117 per acre in the case of the Scottish Assam, and yet the latter divided 5 per cent! The crop ranged from 2,569,000 lb. in the case of the Assam Company to 77,899 lb. gathered by the Lebong Tea Company. But what readers in Ceylon will regard with special interest are the figures for yield per acre. The very highest is so exceptional that it can scarcely be counted for an average. The Doom Dooma Tea Company had a yield of 617 lb. per acre, but this tea sold for only 1s ½d per lb., a case of coarse plucking probably. The results were a profit per acre of £2 12s 8d and a dividend of 2¾ per cent. The next case of high yield per acre, the Borelli Tea Company with 535 lb., shows a selling price of 1s 2d and a dividend of 8 per cent. The selling price here is too good for coarse plucking. The next highest after the two quoted is the Dejoo Tea Company with 390 lb per acre and a dividend of 7 per cent. The very best results in profit per acre and dividend is the Borokai Tea Company with £9 3s 7d per acre and 15 per cent. In this case the tea cost 1s per lb and realized 1s 8d. The yield per acre was the lowest, 265 lb. In the case of the Assam Company, they divided 14 per cent, although their profit per acre was only £3 8s 5d and the tea which sold at 1s 1d cost 11½d to make. The highest cost of production was 1s 1½d, going down from this to 10½d. The highest price realized was 1s 8d, shading down to 11½d in the case which leaves room for a suspicion of coarse plucking. The dividends vary from 15, 14, 12½ and 9 per cent, down to *nil*, 2¾, 3 and 5.

Until we have public tea companies in Ceylon whose accounts must be published, we cannot institute comparisons, fully and fairly; but, certainly, if 265 lb. per acre yields a profit of £9 3s 7d per acre and a dividend of 15 per cent in India, we think Ceylon estates, with twice the yield, ought to do better. We append the table:—

LONDON TEA COMPANIES

(*Arranged according to area of cultivation.*)

RESULTS OF WORKING IN 1883.

THE GIBBS & BARRY TEA-DRIER.

We are obliged to the gentleman who has sent us copy of a pamphlet containing a description of this great tea-drier, which is to estates making 1,000 maunds or more per annum what a small sirocco is to a property turning out only 100 maunds. Conspicuous in the pamphlet is an extract from the speech of the Chairman of the Assam Company, stating that the Company had waited for a machine such as this, which was a perfect success. By means of coke fuel, it will turn out about 2½ maunds (200 lb.) of three-fourths finished tea per hour, the tea being fully finished over choolas or in a sirocco. It also rapidly prepares tea for finally packing. It is claimed for this cylindrical machine that it acts as roller as well as drier, giving a fine twist to tea leaves and being a substitute for the old copper pans with which tea used to be finished off. At a temperature of 700° (!) the tea passes through the cylinder in ten minutes, from ¼ lb. to ½ lb. of coke being used for every pound of tea. Coke seems a necessity so we hope Colombo will be able to afford to consume plenty of gas by the time many of these machines are needed in Ceylon. There are high testimonials to the value of the big driers, the only fault being its high cost. But it does work in proportion.

This machine is said to be the best hitherto produced for drying grain and seeds as well as tea. It is said to have been widely used in India during the past three years and to give increasing satisfaction. A number of very favourable testimonials are printed in the pamphlet which contains the following description:—

The machine is simple in construction, can be easily put together, and with care and proper attention should give no trouble. It may be briefly described as a rotating cylinder in the axis of which is placed a perforated

tube for conducting the hot air or gas which is forced into it by a fan. The interior of the cylinder is fitted with shelves, and the apparatus is placed on an incline. The green leaf is fed in at one end of the cylinder, is constantly carried up by the shelves, and allowed to fall through the current of hot air as the cylinder revolves, thus travelling down to the other or lower end, where it is discharged in a nearly dry state. It can be brought out fully dried, but the Patentees recommend it to be never more than "seven-eighths-fired" when it is discharged from the cylinder, and the final firing to be completed in trays over ordinary "choolas." They prefer the tea to be brought out about "three-fourths-dried."

It is not claimed that tea dried in this machine is superior to all other machine-dried teas, but, as the process is automatic, and consequently must, if ordinary care be bestowed, ensure absolute uniformity, it is asserted that it produces tea certainly not inferior to that made by any other known apparatus.

Further on, fortunately, we find it stated that the tea can be just as well finished in siroccos for which ordinary wood-fuel will suffice instead of over charcoal in the old "choolas" or furnaces. Charcoal is troublesome and expensive to make and store, and the great advantage of the sirocco and other driers on the same principle is that charcoal can be dispensed with and wood-fuel used, or even straw and grass where fuel is scarce. Coke seems to be essential for the Gibbs & Barry machine, as the heat seems to be drawn or rather projected through the cylinder directly from the fire by means of fans. But, even if coke can be procured in Calcutta, it must cost a good deal to transport it to estates in Darjiling, and still further away in Assam, Cachar and Sylhet. If the coke has first to be imported from Europe, however, we fail to see how the merit of economy can be so strongly insisted on. The cost of the machine is pretty heavy to begin with, and, in order to erect it, 300 fire bricks, 6,000 common red-bricks and 1 cask clay will be needed. Then comes the cost of the coke fuel. The article here in Ceylon will be scarce and dear in proportion, as the Municipality persevere in their policy of economy in the use of gas, a policy of which the representatives of the Gas Company so bitterly complain. The process where the Gibbs & Barry machine is used seems to be this: the tea, when properly withered, rolled and fermented, is put through the cylindrical machine, and the strong recommendation of the inventors is that it be never more than seven-eighths fired in their machine. It should then be finished off over charcoal furnaces or in a sirocco. Before being packed, the tea is again put through the machine and "pucka-bhattied," as the Hindustani slang has it for final or permanent finish. The patentees claim that, for this process, their drier has been eminently successful. "As many as 30 maunds of tea have passed through it in an hour." Of course, dried tea from the bin is here meant. As to the temporary or "kutcha-batty" work done by the machine, its inventors state:—

The quantity of tea which can be dried by this machine is very large. There are two sizes; one with a cylinder 18 feet long and 3 feet 6 inches in diameter, capable of "*three-fourths-drying*" about ten maunds of *green leaf* per hour [=to 2½ maunds or 200 lb. made tea.—ED.]. And the other with a cylinder 12 feet long and 2 feet 6 inches in diameter, which will "*three-fourths-dry*" about four maunds of green leaf per hour [=1 maund or 80 lb. dried tea.—ED.]. In stating this, however, the Patentees do not guarantee any particular results. In some cases these quantities have been exceeded, while in others they have not been reached.

Of course, a good deal depends on the operator, and in the pamphlet there is a statement of results by a planter who partially prepared the bulk of his tea by this machine and finished a certain quantity by its means. This gentleman, Mr. Wm. Aitchison, of Dooloo estate, discloses the reason why the patentees object to the drying process being completed in the cylinder, *the tendency of the tea to turn grey*. Can this be due to the tremendous heat of 400° to 700° against the 280° to 300° of the sirocco? Mr. Aitchison, writing eleven months ago, said:—

"I can get the results you mention, 2½ mds. per hour ¾th dried, and I think I could easily get 1½ mds. per hour fully dried tea. If I had another machine I think I would fully dry the tea in them; for I find after some experience in the working of it that the tea could be fully dried and yet not be made grey, or at least very little. I would let the tea come from the cylinder 15½ annas, or so, dried, and the heat that was then in it would be quite sufficient to make it crisp by the time it was cool."

Then follows a figured table from which we learn that in the case of the tea which was finished in the cylinder the expenditure of coke was 9 maunds for 11·6 of dried tea; 13 maunds for 17·60 and 8 maunds for 12·50 maunds tea. In this last case the consumption of coke per maund of tea was so low as ·64; in the other cases the proportions were ·73 and ·76. The result is that somewhat less than three-fourths of a maund of coke, or so say 71 lb. of coke, were used for each maund of 80 lb. of dried tea; that is, less than ¾ lb. of coke for each pound of finished tea. In this case no charcoal was used. The average quantity of dried tea turned out per hour varied from 1·18 maund to 1·41. If further experience or further improvements effected show that the tea can be finished off in the one machine, it will be a great convenience. As matters stand, we suppose that in every factory where a Gibbs & Barry (large size) is used there ought to be two siroccos; with one for the small size. We cannot conceive of anyone who has had experience of charcoal furnaces reverting to them. Mr. Aitchison used them, however, for the tea partially-finished in the cylinder, with the result that almost as much charcoal was used to finish as it took coke to partially prepare the tea. In one case the proportion of coke to charcoal was ·39 maund coke and ·36 charcoal to 1 dry tea.

Again	·36	do	·36 do
Finally	·27	do	·45 do

The total in the first case was ·75: in the second and third ·72 respectively. We therefore get ·73 and a fraction, or less than ¾ maund of coke and charcoal for 1 maund dried tea: less than ¾ lb. of the united fuel for 1 lb. dried tea. The quantity dried per hour by both processes varied from 2·79 maunds to 2·92 and 3·23. In the latter case a quantity close on 360 lb. per hour, or 3,600 for a day of ten hours. The proportion of fuel, that fuel being in both cases the carbon remaining after the expulsion of bulky extraneous matter, was very moderate. The whole question, then, is the cost at which the coke and charcoal (where the latter is used) can be laid down at the mouth of the furnace. We would simply remark that where firewood for siroccos is plentiful, 2 lb. of firewood for each pound of tea is not likely to cost more than ¾ lb. of coke or charcoal. Except those who still retain a belief in the virtues of charcoal fumes, we suppose the decision of all planters in Ceylon who resolve on using one of the cylindrical machines will be to have a sirocco or siroccos to finish off with. Mr. James Inglis, writing from Dilkhoosha on 11th June 1882, stated:—

In reply to your queries—"whether the tea is improved by being passed through the machine":—

The tea is certainly vastly improved in appearance. Machine rolled tea is generally, or I may say always, very straight, and in sorting passes so easily through a sieve that it takes a large bold appearance. Being passed through the dryer it takes on a curl, which gives it exactly the look of hand-rolled tea, and the sorting becomes more even.

I would not at present give you any decided opinion

as to whether the flavour is improved, but it does certainly enable us to give the tea any degree of fermentation required, as that process is at once stopped when the leaf is thrown into the machine.

The cells do not impede the passage of the tea through the cylinder, and the only chance of the tea being burnt I consider depends altogether on *irregularity* of feeding and temperature, speed of fan and cylinder and the inclination of girder; we burnt a little tea the first few days, but since then we have not burnt any.

Again on the 17th :—

The Dryer.—We are keeping careful satistics of this machine, which shall be rendered at the end of the month. The following is yesterday's working:—

Tea dried, almost finished 1,371 lb.

Time occupied 9 hours 10 minutes.

Coke consumed 560 lb.

It is the new machine we are working, and I like it very much. I don't think there is any more risk in burning the tea in it than over charcoal. We bring the tea out almost finished, and finish it over charcoal or coke—half a maund was the amount of coke used in finishing the above 1,371 lb.

So that in this case 600 lb. of coke sufficed for the finishing of 1,371 lb. of tea, or considerably less than ½ lb. fuel for each pound of tea. To quote Mr. Inglis again :—

Our system is as follows :—

We pack 30 to 45 chests at a time.

When steam is got up in the morning the furnace is lighted, and when the heat is up to 400° we begin to shovel in the tea as fast as a man can do it. The elevation of cylinder is 6 inches, and it revolves about 10 per minute. The tea takes 10 minutes in passing through, and comes out so hot that one cannot put one's hand in it. The amount of tea is from 16 to 18 maunds per hour, we could easily do more than this if we wished. Rolling begins with pucka-bhatty, so by the time we have passed 40 maunds through the cylinder the green leaf is coloured and ready for firing, so by this plan we lose neither time nor fuel.

The tea pucka-bhattied by the cylinder gets at the same time a good cleaning, and the amount of fibro, &c., blown out at the end is considerable.

A great deal depends on the withering of the leaf as to the quantity of tea the cylinder will dry in an hour, as is natural to suppose well withered leaf is easier to dry. Indigenous leaf is again more difficult to dry than China.

And then comes Mr. S. M. Barry's testimony, in a letter dated 3rd July 1883, that whatever was gained by the old process of panning the teas, to which the Chinese and Japanese still adhere, can be secured by the use of the cylindrical drier :—

The flanges or plates over the heated air-duct represent the heated pans, and from the rotary action of the machine the rolled leaf is far more evenly tossed than could be done by hand in a pan, and comes regularly in contact with the heated flanges. Also as to twist; the leaf having to roll down the sloping side of the air-duct over the heated flanges represents the rubbing process in pans, and the tea acquires the most perfect twist and curl that could be desired. As an experiment, I have put half-rolled leaf through the Dryer, and the tea came out with a much superior twist and curl than very hard rolled leaf dried over the ordinary Choolas.—Indeed, the fact that our chests hold 12 to 15 per cent. more of the same classes of tea than formerly shows how much closer the leaf is twisted by the action of the G. & B. Dryer. We had a little difficulty with the furnace at first, but have now got over that. By placing two or three kutcha bricks on end at each side of the furnace, it prevents the molten coke coming in contact with the fire-bricks, and when drawing the fire, every thing comes away quite clean. These bricks are also the means of saving coke, as, owing to the large furnace, we could not do with less than ½ md. coke to md. of tea, and we can now do with less than ¼ maund.

The fire-bars I don't consider necessary, and do not use them at all. The Machine can do the work stipulated quite easily, indeed I have done 12 mds. leaf per hour without trouble.

Another superintendent states : "It saves labour by 80 per cent." Here is Mr. Barry's reference to a temperature of 700° :—

We have been working eight hours today at 700°, and putting through, I calculate, about 14 maunds leaf per hour, and doing it to perfection.

Mr. E. F. Skinner wrote—

"I consider the Gibbs and Barry Dryer able to more than three quarter dry 30 mds. of tea a day in wet weather and over 35 maunds in dry weather."

"The consumption of coke for 45 days has been 419 maunds, which is about equivalent to 25 lb. per maund over ½ lb."

"The cost of working the Dryer R22 per month. Taking into account the finishing off of the tea per Sirroccos I estimate the Gibbs and Barry equal to 5 Sirroccos. The cost of working this number in my tea-house is R88 per month.

I am much pleased with the working of the Gibbs; I believe, I can make it do more than it at present does, the driving pulley I have being a little too small. Although a few improvements remain to be in the Gibbs and Barry, I consider it by far the best dryer I know of. The Sirocco does its work perfectly, but owing to the great expense entailed every year for repairs and the cost of working it being great, I consider Gibbs and Barry much preferable."

Mr. T. Henderson wrote :—

The only improvements I can suggest are first in the chulahs, which might be made so as to resist the great heat better.

And second in the price, which I hope the Patentee will see his way to reduce.

Finally the patentees say :—

The large quantity of tea it is capable of manufacturing, regularity in quality, convenience and simplicity in working, and economy in labour and fuel, are claimed as advantages peculiar to this machine, and place the "Gibbs and Barry" tea dryer in front of all its competitors.

We have thus, for the benefit of our readers, given Messrs. Gibbs & Barry one of the best possible advertisements, for which they may or may not be more grateful than the patentees of some other machines who wrote to their agents to get their machinery noticed in the *Ceylon Observer*, "but not by way of advertisement"! We need scarcely say that the *Observer* is not likely to go out of its way again to notice the machinery of the firm referred to, and this we believe will be no loss to our readers.

TEA PICKINGS.—FERMENTATION.

Since last writing we have come across the following 'Tea Note' from Upper Suddiya in the *Indigo Gazette* :—

Everyone has been trusting to being supplied by the Railway Company with coal and coke, but even in this they are sadly disappointed, and the large amount of the latter offered for sale by the I. G. S. N. Company is at present unfortunately submerged in the river at Dibru Ghat.

We are all praying that our Paternal Government would take the railway over; it could not be more badly managed than it is now in this *up-hill* manner.

So that even in India, where coke is more freely obtained than here, it is not safe to have a machine that depends entirely upon that fuel for the feeding of its flames to fire the tea. But we find that we must no longer unscientifically talk about tea firing. A Darjiling planter says it is really dessication; and in a supplement upon tea machinery which we gave with our issue of June 17th, we were told in regard to fermentation that "the chemical process through which the leaf passes is not in the least akin to fermentation," but that it is oxygenated." To the tyro in tea cultivation we would therefore offer the following explanation of the necessary manipulation. 1st Decapitation (Picking) : 2nd Siccation (Withering) : 3rd Circulation and Maceration combined (Rolling) : 5th Dessiccation (Firing) : 6th Separation (Sifting) : 7th Combination (Packing) : 9th Embarcation (Shipping) : 10th Venditation (Sale) : 11th Realization (Profits) : 12th Jubilation (*i.e.* a trip home to see one's *mother*). We have not Rogets'

Thesaurus at hand, or we might have gone to deeper depths, or rather greater heights still.

With regard to Fermentation the Darjeeling correspondent of the *Indigo Gazette* rightly says that there can be no hard and fast rule laid down as to how long tea takes to ferment properly. When the weather is dry and hot, it will ferment much more quickly than in wet weather. Again the state of withering has a great deal to say to the length of time it will take. We contend that the eye is the best test to go by, and the color, if caught at the right moment will come out exactly the same color in the infusion that it did when it was put on the fires or into the drying machine." To the test of the eye we would add that of the nose, and with a little practice of these two senses combined the obtaining of a good and equal fermentation is rendered a certainty. "A Nilgiri Tea Planter," in the pamphlet issued by us, says :—

Many planters colour their tea loose and in heaps. I never do so at first, but only when I see that the cones are not colouring evenly throughout, and then the business must be conducted with great care. This operation is a most important one, and only lengthened experience will enable the planter to do it readily to the exact pitch required. Time is no test at all. I have coloured tea on these Hills in 1½ hour; whereas on another occasion I have known it stand in the cones for eight hours and scarcely take any colour at all. The temperature of the house and the quality of the leaf are the main points to go by. I find that at an average elevation of 5,500 feet in an iron-roofed factory the thermometer will range from 70° to 86°: and the time taken to colour the leaf under a single fold of blanket will vary from 2½ to 1½ hours.

On Abhotsford, at 5,800 feet, the roll is fermented in baskets, and in wet weather we have some times had it stand as long as eight hours ; but the usual time up there is, according to the dryness and warmth of the temperature, from two to four hours. Mr. H. Cottam, in 'Tea cultivation in Assam,' another pamphlet issued by the *Ceylon Observer* press, remarks :—

Tea leaf is sometimes rolled after fermentation, but this plan is not generally approved of, and is going out of fashion, being not considered safe, and liable to unroll the leaf, as well as being a waste of labour.

Cases have been known of planters not having proper firing conveniences and being unable to fire the leaf quick enough, consequently their tea has "gone sour" through standing nearly half a day in an over fermented state.

In hot weather tea will turn sour in two hours or so.

The mode of judging the time allowed for fermentation is by watching the colour of the leaf, which should turn from brown to a salmon or copper colour.

If left too long, the outside becomes a greenish black and makes a black tea after firing.

At one factory of the Assam Company, I saw the leaf placed in bottomless boxes, and pressed tightly down; the boxes were afterwards removed, leaving the pressed tea leaf the shape of a brick.

In another factory, baskets are used and tea leaf jumped upon until the basket can hold no more, then turned upside down and left to ferment.

The larger the quantity put together for fermentation, the better; for one reason, coolies are apt to play with the small balls and keep on twisting and turning them and wasting much time.

We do not altogether agree with the observation upon rolling after fermentation. We know that with us it has been found that a much finer tea has been turned out by the following process. The roll, when half finished is taken out, all the small leaf sifted and put to ferment separately : the remaining larger leaf is left to ferment slightly, then put back into the roller, and finally fermented fully. By this means very fine tip is obtained, the red leaf is almost nil, and every souchong leaf is as well twisted as the pekoe. This practically is the process recommended by Mr. Owen, who gives fermentation yet another appellation,—oxidation. He says, "Regarding so-called fermentation—for I believe this to be a misnomer and that oxidation would be a more correct term—it is a good plan to mix the roll several times during the process, as this makes the color much more even. In fact, in a hot climate, I would employ boys in turning the roll over constantly, and I have seen some of the best manufactured teas in Assam and the Terai made this way. It is not a bad plan, after machine rolling, to sift the roll through a No. 4 sieve and ferment the small and big leaf separately ; this will enable you to color your coarse souchong leaf without overdoing the pekoe and broken. When roll is constantly turned however (and it is quite practicable when color is obtained in an hour or so) this sifting is unnecessary, an even color being obtained without it." In this decided expression of opinion, as to constantly turning the leaf being better than sifting it, we think Mr. Owen is wrong, for one of the strictest axioms of tea manufacture laid down is that the less the leaf (at *all* stages) is handled the better. Mr. Armstrong's remarks on this subject are so very valuable that we have no compunction in taking them over in full. They are as follows :—

"After your leaf is sufficiently rolled, break up the roll well, so as to have no lumps in it, and place it lightly in saucer-shaped baskets of bamboo, or cane, 18 inches wide by 6 inches deep; these again to be placed inside a sack to ferment. Each basket holds about 12 lb. of roll —no actual time can be laid down for fermentation, as it all depends upon the day or time of year. In cold weather, at 5,600 feet, I have waited for 6½ hours for it to ferment, although my house has been kept at 90°. Again, at low elevations, I have seen roll properly fermented in 20 minutes from rolling. As far as time is concerned, at high elevations in ordinary weather, I find it takes from 1½ to 3 hours. Machine-rolled ferments quicker than hand, an advantage in favour of machine. Roll is properly fermented when it shows at a *first* glance a bright new copper color. We must not in making this test, examine the roll too carefully as, if we do, we will find almost as many green as copper-colored leaves ; the *first* glance on taking up a handful must decide us. As a rule, we should ferment up to our pekoe souchong and let the rest take care of itself ; if in doubt, under ferment rather than over ferment ; over fermentation may cause the tea to be altogether sour, and in any case gives a dark-colored, flat liquor, with dark, dead-looking infusion. For the first two or three rounds after pruning, our leaf will not give us a very bright infusion, and there is no use waiting on the fermentation to try and get it ; all comes right as the wood matures. Having arrived at a proper state of fermentation we should hand-roll lightly again, even if machinery is used. Coolies employed in the factory, firing, withering &c. &c, are sufficient to do this. It is necessary, as it inclines the roll, opened more or less by fermentation, to take its twist again as it is being fired, and it also ensures the whole being thoroughly well separated, before being placed in the firing trays."

We would draw special attention to the two important facts mentioned above: that machine-rolled ferments quicker than hand-rolled tea, and that the state of fermentation is to be judged of not by a close examination of the roll, but by a quick superficial glance.

Returning to the letter in the *Indigo Gazette*, we find the following sensible remarks made :—"For one fill of an ordinary Jackson's roller, we find that a space of, say 20 feet and three feet, will not be found inconvenient, and will enable the fermenting leaf to be put out about the proper thickness. The leaf should, after it is turned out of the rolling machine and put upon the table to ferment, be covered over. It is also most important, at the end of each day's work, to have the fermenting tables scalded with

hot water from the engine, and thoroughly swept clean and dried. The boiling hot water from the engine dissolves any coagulation of juice there may be, and renders it easily removed, whereas it would not yield to cold water, and if the latter is used, in a short time the stench from the tables would be very bad, and although it might go on for sometime without materially altering the value of the teas, it would still be apt to create a prejudice against teas otherwise most carefully manufactured." And in conclusion (and it must be our conclusion too, for today), he says, with regard to fermentation, "we do not think there is very much more to say, except that planters should beware of fermenting China leaves as much as Hybrid; for if this is done, the China leaf somehow loses all its sharpness and briskness, even if we cannot go the length of calling it pungency, and coming into contact with fully fermented Hybrid or indigenous teas, suffers very much in comparison. It should be remembered, then, that it is always safer with regard to China tea to have it rather under than over-fermented; for whilst a tea made from Hybrid indigenous plant gains in thickness and strength, a tea made from China plant gets dull and flat, by no means desirable qualities."

THE RAINFALL FOR THE FIRST HALF OF 1884.

Through the courtesy of the Public Works Department, we are able to publish a table of rainfall for the first six months of 1884 at many of the principal stations in Ceylon, by which our readers will see that in nearly every case the deficiency on the averages established by the results of similar periods in previous years is very great. There has been some delay in publishing this return which was so promptly furnished at our request, in consequence of the P. W. D. return from Nuwara Eliya being imperfect. A reference to the Surveyor-General's Department has brought us, not only the correct figures for Nuwara Eliya and the average, but the results obtained at Hakgala, a new station, where the observations are taken by Mr. Nock of the Government Gardens. Nuwara Eliya is on the midway table-land which divides Dimbula and neighbouring districts from Uva. Hakgala is a grand isolated mountain at a distance of seven miles from Nuwara Eliya by the road to Uva. Mr. Clements Markham fixed on a plateau under the summit of this mountain for the commencement of the cinchona experiment in Ceylon; and now that there is no further occasion for special attention to cinchonas, except the rarer kinds, Mr. Nock is with great success cultivating, for distribution, numbers of plants belonging to temperate as well as tropical and sub tropical regions. The elevation of the spot in the Gardens at which the observations are taken is 5,581 feet, or 659 feet below Nuwara Eliya which is 6,240 feet above sea-level. A comparison of the results obtained at two places so close together and yet with topographica conditions so different (Nuwara Eliya being an elevated plain, inside an amphitheatre of hills, while Hakgala is an isolated mountain facing and dominating the vast plain of Uva) cannot but be interesting. Here are the figures :—

MONTHS.	NUWARA ELIYA.	HAKGALA.
	Inches.	*Inches.*
January... ...	... 1·49	4·67
February ...	... 0·24	1·85
March	... 3·19	3·90
April	... 3·17	3·02
May	... 5·01	4·48
June	... 4·88	2·53
Total...	17·98	20·15

The rainfall at Nuwara Eliya to 30th June 1884 was short of the average of 14 years (39·34 inches) by considerably more than one-half. Hakgala being a new station has no average to show, but, looking at its position, head and shoulders above all around it, we are not surprized to find that, short as the rainfall has been, an excess of somewhat over 2 inches is shown in favour of Hakgala over the hill encircled upland plain. Still the drought must be very trying to many of the numerous plants which Mr. Nock is so arduously and so intelligently striving to acclimatize and grow.

As we take the figures for station after station occupied by officers of the P. W. D., the drought of the first half of 1884 becomes only the more apparent. Colombo is not included in these P. W. D. returns, but we know from the figures supplied by the Surveyor-General that the rainfall at the capital was one-third short of the average of 14 years : 27·85 inches only against 41·10. At Negombo the total was 21·90 against an average of 33·74; Awisawella 55·70 against 74·44; Kalutara 32·72 against 48·57; Padupola (the rainest station in Ceylon) only 43·25 against 83·10; Pelmadulla 68·91 against 69·45 (no appreciable falling off); Nawalapitiya 45·22 instead of 56·75; Katugastota 16·89 against 37·98; Matale 15·40 against 35·55; Dikoya 51·01 against 50·00, or, in this exceptional case 1 inch above the average! Dimbula, however, which marches with Dikoya, although it is further away from "the Peak," received only 33·14 inches instead of the average of 51·60. Dikoya seems to have intercepted the rainfall which ought to have passed on to Dimbula. The Nuwara Eliya and Passellawa returns are imperfect. Haldummulla got 49·79 inches, but no average is shown. We should say the rainfall in this case was ample; but Badulla shows a beggarly account of only 17·01 inches for the six months. This means severe drought. Kurunegala had little more than half the average, 22·89 against 41·38, while Chilaw showed 14·66 against 22·87. Puttalam had only half the average, 8·44 against 16·23. But the case of Mullaittivu was deplorable: only 2·97 inches against 12·63. Jaffna got 4·49 instead of 7·77; but Vavuniya Vilankulam showed only 7·96 against 15·66. Mannar got only 2 inches of rain in six months, instead of the low enough average of 10·75; but Mannar is the most arid place in Ceylon. Mihintale got 11·59 against an average of 15·21 while Tangalla got 20·70 in lieu of 26·56. Tissamaharama got 10·25 instead of 16·72, and Matara 23·34 against 27·90. Galle received only 33·67 against 52·03, and Hambantota (the next driest station to Mannar) 4·57 instead of 10·50. Irakkaman showed 14·50 instead of 21·35, and Rukam 12·94 as compared with 18·32. Kalmunai showed 11·50 as against 14·34, and, though last not least, Trincomalee 6·94 instead of 14·88.

In this list of 32 stations, only at one, Dikoya, did the rainfall exceed the average (an exception which we cannot understand), and in one other case the deficiency was small. In the vast majority of cases, the deficiency ranged from one-half to one-third on the averages. There is reason, therefore, to apprehend that either August and September will be very wet months, or that we shall have an excessively rainy north-east monsoon. July made but feeble attempts to supply the deficiency of the six months. We must just watch and wait for the swing of the pendulum. As a general rule, seasons right themselves and give averages of rainfall in periods of five years.

P. W. D. RETURNS OF RAINFALL FOR THE FIRST HALF OF 1884 WITH THE AVERAGES OF CORRESPONDING PERIODS FOR A SERIES OF YEARS.

WOOD FOR TEA CHESTS.

We take over from the *Madras Mail* a very important memorandum by Dr. Watt upon the above subject, but Dr. Watt being as yet no more perfect than the tea machinery of which he speaks so disparagingly, we are tempted to give his article a little touch up with our critical whip, before discoursing upon its really excellent points. As we read we cannot help feeling as though the writer had, for some reason or other, a secret animus against the unfortunate tea-planter: otherwise it is hard to explain the *raison d'être* of such sentences as these :—"The fault may not improbably rest with the planter himself;" "tea-planting, *including the out-door work*, as well as the curing at the present date seems to be in the same position as brewing was in Europe half-a-century ago;" "the preparation of tea upon a scientific principle seems a not very distant future." The last remark would have called forth more gratitude, perhaps, had a little explanation of its meaning been added. As it stands, we may assert that no planter, with any true ambition in his soul, desires that in the near or distant future, all teas, whether Assam, Darjeeling, Ceylon, or Java, shall be made on so scientific a principle that the state of the market alone would determine whether they should all alike obtain 2s 6d per lb. or 1s 6d per lb. All need for exercising one's own wits and all healthy rivalry would be put an end to, and the planter would become merely part of the necessary estate machinery.

Again, if the Government of India have correctly reported Dr. Watt, his style of composition is capable of improvement. He says that "the *Indian* tea-chests are as carefully made in India as *in China*"; that "it may be the tea itself which corrodes the metal and not the wood" (what he means is that "it may be the tea itself, and not the wood, which corrodes the metal"); and he "had *the pleasure* of inspecting lead said to have been corroded through the action of the wood." This is like the editor who "*regretted* to say that his report of the death of Mr. —— turned out to be incorrect, that gentleman being in his usual" &c., &c.

We, now, have *the pleasure* (real, this time) of noticing the very valuable results obtained by Dr. Watt from his experiments with wood and lead, and we are sure all planters will join in a vote of thanks to him for his trouble. The most important result obtained is certainly that he "failed utterly to discover any wood which seemed to possess the least chemical action upon lead." If further researches thoroughly establish this fact, the advantage accruing to the planting community will be that inferior timber woods, hitherto rejected for their supposed corrosive properties, will go to swell the supply needed to meet the great demand, which is at present made upon the better species of timber trees for the construction of tea-boxes. The damping of the wood experimented upon was a much severer test than, we trust, tea-boxes usually have to undergo, but it did good in conclusively proving that the damp in the wood escapes into the outer atmosphere and does not penetrate through the lead, unless, of course, there be holes in the latter through careless soldering or other causes. In this connection we here insert an extract from a Darjeeling letter which we have just come across in the *Indigo and Tea Planters' Gazette* :—

While on the subject of tea, I may as well mention a new lining for tea boxes, which has been patented by Mr. Linberry, of the Dooktaloo tea estate. Every practical man knows that the lead lining at present universally employed in this country is expensive, and at the best, unsatisfactory. Mr. Linberry's casing is made of the Willesden waterproof paper, lined on the inside with tin foil. It is claimed for this invention that it is absolutely water-tight, costs much less than the sheet lead, can be slipped into

a box in less than half a minute, and requires but little solder. Most men I have met predict great things for this casing, and many of them are subjecting it to very crucial trials, such as standing the box of tea with the patents casing in a tub of water for a few weeks, exposing it to the sun and rain on the roofs of their houses, &c., &c. I have not heard the results yet, but will let your readers know them before long—at all events, it Mr. Linberry's invention stands the tests, he will certainly have solved one of the great bothers that have been perplexing Indian tea planters almost since the starting of the industry in India; as, if the package proves to be absolutely air and water tight, it will be of no consequence whatever what wood the boxes are made of.

At the Calcutta Exhibition our special correspondent saw a trough of Willesden paper that had held water for *seven years*, and it was apparently as good as ever. If this new experiment proves a success, why should boxes be used at all, for the Willesdon paper, being strong enough to build houses and roof goods-sheds with, it would surely stand the moderate amount of rough handling it would have to undergo in the shape of a tea-chest!

Returning to Dr. Watt, he says with regard to the supposed corrosive influence of the woods that "if the question were merely one of flavour imparted to the tea, one would expect the pine wood used in China to stand first in this respect." The pine used in China, however, has, we believe, very little resinous matter in it and we have seen it stated that it is seasoned for two years before use. It will cause planters to pay very particular attention to the firing of their tea, and more especially to their *pucka battying*, or final firing, when they learn that Dr. Watt's conclusions are that in every case corrosion of the lead commenced upon *the inside*, and was due consequently to the imperfect expulsion of all moisture from the tea, or interior of the leaded box, before packing. We would suggest the suspension for a few minutes of a charcoal brazier within the chest about to be packed: the hot tea then poured in and the box immediately soldered down. Given the tea perfectly dry this process ought to reduce to a minimum the chances of damp air arising in the shape of acids and forming corroding salts on the interior of the lead lining. As Dr. Watt says, it is some time now since the injurious action upon tea of all iron in the shape of nails, screws, &c., was discovered, and Jackson's Roller's are now made upon the principle that the rolled tea comes in contact with nothing but wood.

The following is Dr. Watt's article, as contained in the *Madras Mail*:—

The following memorandum by Dr. Watt (on special duty with the Agricultural Department) on woods used for tea boxes, has been published by the Government of India, for information in continuation of previous correspondence on the subject:—

My views on the subject of woods suitable for tea boxes (which I hope to fully express in the dictionary of the economic products of India, now under preparation) are at variance with the popular outcry against our Indian timbers as injuring the Indian teas, I may therefore be pardoned the liberty of briefly indicating the results of a few personal experiments. It seems to me that the fault may not improbably rest in some part with the planter himself, or rather with some imperfection in the system adopted by him to cure his tea. The climate of India, and more particularly of Assam, in point of humidity is utterly unlike that of the tea districts of China. The introduction of advanced machinery to lessen the expense of labour would seem to augment the climatic influences upon the manufactured article. The results of a few chemical experiments have led me to the conclusion that the Chinese tea differs from the Indian tea materially, and that this difference is the result in all probability of the system of preparing the tea, combined with the climatic conditions under which the tea is prepared. I have been, through the kindness of one or two tea merchants, permitted to inspect samples of tea and also chests in an injured condition, and I feel confident that more extensive experiments and an extended inspection and chemical examination of injured tea and tea chests would lead to a solution of the difficulty. I have observed the following curious facts:—

(*a*) The tea may be completely destroyed, and yet upon the most careful scrutiny not a single opening can be detected in the lead. It is obvious that until the lead is corroded through or perforated, any injurious influence which the timber might exert upon the tea could not take place. If the lead lining through carelessness be imperfectly soldered, then the tea might be injured by the wood; but this would be but a just punishment, and the planter would have himself to blame. I am confident, however, that this is rarely, if ever, the case, and I quite agree with Mr. Mann in his opinion that the Indian tea chests are as carefully and neatly made in India as in China, the more so since their imperfections are not covered by fancy-coloured papers.

(*b*) I have on several occasions had the pleasure of inspecting lead said to have been corroded through the action of the wood. I have not seen a lead-lining completely perforated, but it is curious that the fact that the action seems to commence on the inside of the lead instead of on the outside, or on the surface in contact with the wood (the supposed acid influence which decomposes the metal), has not been apparently observed. This fact alone should have suggested a very different conclusion from that which generally prevails. My opportunities of examining tea chests, and of chemically working out the questions connected this subject, have been too imperfect and too limited, however, to authorize me doing more than to suggest that *it may be the tea itself which corrodes the metal and not the wood.*

(*c*) In favour of this suggestion, I may mention that there are one or two double organic (chemical) compounds which are well known to chemists to have the power to act as acids to metals, and thereby produce salts, thus corroding metals. This fact as an established principle of his art, is well known to the planter. It is some time now since the action of the iron nails, screws, &c., was perceived by the planter to be injurious and in his tables and machinery these are by the experienced planter carefully covered over or protected.

While I am unable to establish the conclusions I have arrived at upon a definite and chemical basis I think I have said enough to give a new turn to this enquiry. The fact is tea planting, including the out-door work, as well as the curing at the present date seems to be in the same position as brewing was in Europe half-a-century ago. The process of fermentation and curing of tea is a purely chemical one, and it may be suggested that, instead of feeling, smelling and judging by colour the planter might also employ scientific apparatus to determine for himself when the process (in each stage) has been carried to the correct extent. It would seem at first sight quite impossible for the tea to get damp, presuming it to be carefully dried and carefully soldered down. Still however, experience has shown that tea will get damp as at present exported, even when both these conditions have been carefully observed. This must be due to the humidity of the air enclosed within the lead lining, establishing within the chest a renewal of the process of fermentation; and, when once this is established, it is not difficult to account for the corroding of the lead.

I had the opportunity during the Calcutta International Exhibition of inspecting some 200 tea-box woods from all parts of India. Mr. Manson the Forest Officer in charge of these collections, performed, along with me, a large series of experiments. With four slabs of wood, between each pair of which a sheet of new lead was fastened, we tested the supposed action of the wood. One pair was unseasoned wood, the other the same wood, only seasoned. After damping the pairs, they were set aside for a time under circumstances intended to simulate the effects of the hold of a ship. In many cases, such as the silk cotton tree (*shimul*), the wood was completely rotten; in others, firmly attached to the lead through the growth of a fungus from the decomposition of the wood. Others, such as *toon* wood, seemed perfectly unaffected. In no instance was the lead found to be in ever so slight a degree chemically acted upon. These experiments I repeated once or twice after the

close of the exhibition, but failed utterly to discover any wood which seemed to possess the last chemical action upon lead.

That the wood is not the cause of the action seems still further indicated by the fact that in China, as in India, a large number of woods are used, and that there does not seem the slightest evidence, neither in India nor in China, that any of these woods has as yet been shown by experience to corrode the lead. If the question was merely one of flavour imparted to the tea, one would expect the pine wood used in China to stand first in this respect; but what is complained of is the chemical decomposition of the lead lining, and the cause of this might easily enough be determined by chemical analyzis of the tea so destroyed, compared with a chemical examination of the fresh wood used for the boxes, and chemical experiments with the various actions upon lead of the compounds formed from the fermentation of tea. The presence of any active principle amongst the tea which belonged to the wood would prove my explanation to be incorrect; while the establishment definitely of the peculiar compounds from tea which possess the corroding power would lay the foundation for a complete solution of the difficulty. The preparation of tea upon a scientific principle seems a not very distant future.

TEA PICKINGS.

The *Home and Colonial Mail* of July 11th contains a pretty full report of the fourth ordinary general meeting of the Jokai (Assam) Tea Company, Limited; and we have marked for comment those portions of it which, we believe, will be of the greatest interest to our readers. The chairman, enlarging upon and explaining as far as possible the various paragraphs of the report, "drew attention, in the first place, to the outturn for the past year, which he thought the proprietors would all regard as very satisfactory, being 40,028 lb. over the managers' estimates; or, in other words, nearly 30 per cent over last season's crop. This confirmed the statement he had made on previous occasions that their gardens were progressive. They were still very young, the greater portion had not yet arrived at maturity, and for many years to come they might expect increments, if not so large as that of last year, yet very nearly so. Those increases would, however, in future be due to keeping a proper and adequate supply of labour on the gardens, so as to maintain a high state of cultivation." We are glad to see that the Chairman of this Company, Mr. J. Berry White, talks more commonsenseedly than did the Chairman of the Assam Company the other day when he said that it was no use manuring the tea because it sent its tap-root so far down. A high state of cultivation implies manuring, and on this subject a Darjiling planter writes thus sensibly to the *Indigo and Tea Planters' Gazette*:—

There must be a considerable difference between the tea bushes on the Assam Company's gardens and those anywhere else. At the last half-yearly meeting of the Company held in London, a shareholder interrogated the Chairman on the subject of manuring the plants. The great man shut that inquisitive shareholder up as effectually as the G. O. M. does as inquisitive member of the House of Commons. The gentleman who "wanted to know you know" was told in so many words that manure was of no use to tea bushes, as they were like chesnuts and sycamores, the tap roots went down to the virgin soil. The Chairman evidently forgot, or perhaps did not know, that tea bushes have such things as lateral roots spreading out in every direction close under the surface, and that these laterals play a very important part in the nutriment of the plant—probably more important than the tap root. However, shareholders, no more than young members of Parliament, have any right to be inquisitive and ask trivial questions, and if they *will* insist on doing so, they must make up their minds to a snubbing. It seems to be generally argued amongst practical men that the various artificial manures are too expensive for use on a large scale in this district; but a certain amount of manuring is done every cold weather on most gardens in the way of applying cattle manure and vegetable mould, as well as in digging in the jungle thrice or oftener during the rains.

Of course the *jungle* above referred to is what we in Ceylon should call *shedi*, and is simply the undergrowth of grass, weeds, and seedlings of all sorts. We believe it will prove the wisest economy for those who can afford it to keep up a strong force of labour, so that a constant digging may be given to the whole estate, say three or four times in the year. The increase in yield will more than repay the increased expenditure, while it stands to reason that the more luxuriant flush will turn out finer tea. The labour question, by-the-bye, is liable to become a rather serious one in Ceylon as more estates come into bearing, if it is true, as we hear, that even at R12 per head coolies cannot be procured.

But to return to the Jokai Company. Of the total out-turn of 295,528 lb. there were sold in London 292,361 lb., the remainder (3,267 lb.) having been lost in taring. This loss "was just about one per cent. of the out-turn, which was below the average of most other concerns, a fact which testified to the pains taken by their managers and agents. Small as it was he trusted it would be yet further greatly reduced before long, owing to the regulations sanctioned by Her Majesty's Customs, under which all taring in this country (*i. e.* England) would be dispensed with; in other words, the weights as given at the factory would be accepted. By this arrangement, the Company would not only avoid this direct absolute loss but the teas themselves would escape the lose of aroma, freshness, and condition generally, which inevitably followed upon being turned out and left open in the warehouses for several days." In a note to the letter of a correspondent who complains of the large loss he had suffered through taring, although he himself had most carefully bulked all his teas and had sent a certificate to that effect, the editor of the *Home Mail* says, "The word 'bulked" has been so abused by being marked on chests and garden invoices when the bulking has not been all it should have been, that it is no longer relied upon in the Lane, save in cases where gardens or companies have established a reputation." We trust our planters will from the first endeavour to establish such a reputation that "Ceylon Tea" will be the synonym of all that is "honest, true, and of good report."

After touching upon the cost of production, which last year had amounted to 9¾d per lb. in Calcutta, and 11¼d in London, Mr. J. Berry White remarked:—"Referring to the future, he felt bound to say that the whole question of the industry hinged upon that one point—cost of production. He would not venture to say whether prices would or would not improve, but this he felt sure of that in the future their profits would chiefly lie in the direction of reducing the cost of production." He hoped such a reduction would be made not merely by that company, but by the whole tea industry, to the extent of 3d per lb.; and the chief factor he relied upon for this result was machinery. "It was only a few years ago that it cost 1s 7d to 1s 9d a pound to produce tea. That cost had now been brought down to 11¼d in this country (England), and the reduction was to be attributed mainly to machinery. Machinery, however, was still in its infancy, and a great deal of that now being used was far from fully developed. Especially was this the case, not with the rolling, but with the drying machinery. The first really perfect drier had only been introduced during the past twelve month, while within the same period a revolution, practically

speaking, had passed over the industry in connection with the fuel used for drying purposes. Hitherto charcoal had been exclusively used; in future, coke would be employed, with the result that a saving of about one-half would be effected in the cost of fuel, while at the same time better results would be secured. One maund of coke, costing twelve annas (75 cts) went twice as far as the same quantity of charcoal, which according to his experience never cost less than one rupee." So that here we have the important statement made that coke, while costing one quarter less than charcoal does twice the amount of work. We suppose that in Calcutta, where so much gas is consumed, coke can be much more cheaply obtained than it is in Colombo.

In the returns the Chairman had made out he found that the Jokai division made only 30 per cent of fine teas, and the Jameerah division 34½ per cent, whereas he thought they were entitled to look for 40 per cent, and they should keep on impressing their managers till they got it. Forty per cent of pekoes is what Abbotsford gave last year, and we expect it is a fair representation of good average picking.

Referring to the estimated out-turn and expenditure for the current year, the Chairman went on to point out that the total area under cultivation would be some 1,829 acres, from which he felt justified in promising the shareholders an out-turn of at least 600,000 lb. This would be at the rate of 328 lb. per acre, which is a pretty high average for an Indian garden of such a large extent. The Chairman said that "taking these figures as correct an out-turn of 600,000 lb. of tea, and an expenditure as stated equal to 10½d per lb., if they sold the produce for the same price as in the past year, they would realize 3d per lb. profit. That on the estimated out-turn would yield £7,500 profit against £1,300 the past year."

We conclude with the following extracts from the *Indigo Gazette* :—

In Darrang tea is very backward. The weather is hot and cloudy. Cholera is abating, but cattle disease is still prevalent.

In Lakhimpore tea is still backward. Cattle disease and small-pox are reported from North Lakhimpore.

Cachar has experienced intensely hot weather. The prospects of tea are far from favourable. Blight is extending though its scope is limited, and red spider is diminishing.

THE AUSTRALIAN TEA MARKET.

The Melbourne *Age* of July 1st contains an able review by Mr. Robinson, the Commercial Editor, of the Tea Trade for the Colonies generally and for Melbourne specially for the season ended 30th June. The portion of the report which deals with Indian teas imported into Melbourne is as follows :—

INDIAN TEAS.—The heavy fall noticed in our previous report was quickly recovered in 1883-84, but the tea planters of India had received a considerable rebuff in the rates realized for their teas, though the cause was clearly pointed out at the time, and consequently few supplies to speak of reached us this season. Again, though heavy orders for Melbourne at full limits were in the hands of Calcutta agents all through the season, yet, owing to the high prices paid in London, and the brisk demand from that quarter, the colonial orders could not be executed, and the very small quantity that did reach this side from India, though sold at a considerable advance in price, left a loss in every case to the importers.

The following returns will show clearly the large increaae in the consumption of this class of tea in Great Britain, and if Australia wants Indian tea it is evident she must bid up for it against the mother country :—

Deliveries of Indian tea for home consumption in London, for nine months 1st June to 31st March :—

Seasons.	lb.
1883-84	49,402,000
1882-83	46,571,000
1881-32	38,473,000

The estimated import for 1883-84 is 62,000,000 lb

The total imports into the colonies from India and Ceylon stand thus :—

Seasons.	lb.
1883-84	345,550
1882-83	2,251,702
1881-82	979,520
1880-81	671,000

Stocks in bond must be nearly exhausted.

We quite agree with the editor that if the Australians want good Indian teas they must be prepared to pay good prices for them. The market has been spoiled by China rubbish supplied "at a price," but the Indian and Ceylon teas will yet assert themselves. It will be seen, that, from practically nothing in 1879-80, the landings of Indian teas at Melbourne, under the influence of the Exhibition and the operations of the Syndicate, went up to 671,000 lb. in 1880-81 ; 970,000 next season ; culminating with 2,257,000 in 1882-83 and going down to 345,000 in 1883-84. But the remark is made that stocks in bond of this kind must be nearly exhausted. The case is very different with China kinds. At the commencement of the season, there were nearly 5,000,000 in stock in Melbourne, apart from new teas which began to arrive in July. This was the heaviest stock on record and probably 3,000,000 in excess of requirements. The result was disastrous, of course. The editor says :—

We pointed out last season that the imports into all the colonies for the previous three years had been about 3,000,000 lb. in excess of requirements, and it was this accumulated stock that counterbalanced the short export from China for 1883-84, and baffled the speculators in Melbourne when they operated largely in tea, by causing a sudden influxion from the other colonies and London, when common kinds advanced in price.

The imports of China tea into the colonies, which were only 15 millions of pounds in 1879-80, rose suddenly to nearly 23 millions in each of the succeeding years but went down to somewhat under 16 millions in last season :—

In addition to this, in 1882-83, India, Ceylon, Japan and other quarters contributed about 3,000,000 lb. weight whilst in 1883-84 the same place and London added only about 400,000 lb. weight to stocks.

The total imports into Melbourne, the leading market, rose from 8 millions in 1879-80 to 10¼ ; 12½ and 12 millions in succeeding seasons, going down in the season just closed to 9,406,000. The tea delivered for exportation ranged from three to five millions and for home consumption from 5½ to 7½ millions, but, deducting a shipment to London, 7 millions seem to have been the real deliveries for home consumption in the past season. We suppose all the other colonies will make up some 9 to 10 millions. It is stated with reference to the figures 3,127,000 lb. in bond in Melbourne, ·

We commence this season, 1884-85, with a stock in bond fully 1,000,000 lb. weight in excess of wants. Though deliveries for home consumption and export seem large, it must not be overlooked that 1,500,766 lb. first paid duty and then went for drawback ; also that teas were shipped from Sydney to this, and then re-shipped back again, appearing in our export list ; and finally teas shipped per "Amalfi" and "Potosi," from London to Melbourne, also show in our export list.

The usual array of representatives of Eastern houses have visited our shores during the off season, pressing their wares on the coy merchants of the colonies with an assiduity most perplexing when the very small commission charged is duly considered; yet even small as this appears to be, it suffices for a liberal allowance to

locum tenens who influence business. Again, the easy way in which credits are granted to comparative strangers, and often to the injury of the bank's legitimate constituents, creates some consternation and surprise. If there is a good market and the tea can be sold on arrival, the bill drawn against it is taken up, otherwise the unfortunate bank is sometimes left in possession of undesirable stock.

This reveals an unhealthy state of trade and finance. The transactions in Melbourne are thus noticed :—

Sales by auction show a considerable falling off as compared with last season, amounting in the aggregate to 3,380,155 lb. weight, as against 5,454,770 lb. of China teas in 1882-83, as per details below :—

SALES BY AUCTION, 1883-4.

			s.	d.		s.	d.
3,960 lb.	sold	at	0	5	to	0	5¼
51,560 lb.	do	at	0	6	to	0	6½
113,960 lb.	do	at	0	7	to	0	7½
64,200 lb.	do	at	0	7¾	to	0	8
46,920 lb.	do	at	0	8¼	to	0	8½
151,180 lb.	do	at	0	8¾	to	0	9
273,120 lb.	do	at	0	9¼	to	0	9½
266,960 lb.	do	at	0	9¾	to	0	10
368,760 lb.	do	at	0	10¼	to	0	10½
296,880 lb.	do	at	0	10¾	to	0	11
250,120 lb.	do	at	0	11½	to	0	11½
150,560 lb.	do	at	0	11¾	to	1	0
179,160 lb.	do	at	1	0¼	to	1	0½
256,560 lb.	do	at	1	0¾	to	1	1
140,520 lb.	do	at	1	1¼	to	1	1½
115,840 lb.	do	at	1	1¾	to	1	2
92,200 lb.	do	at	1	2¼	to	1	2½

52,515 lb.	do	at	1	6¼	to	1	7
47,115 lb.	do	at	1	7¼	to	1	8
27,090 lb.	do	at	1	8¼	to	1	10
9,810 lb.	do	at	1	10¾	to	2	0
3,380,155 lb.							

N.B.—All damages and resales by auction are, as far as known, excluded from this list.

Or say,

2,038,480 sold at 5d to 1s per lb. in bond.

1,341,675 sold at 1s 0¼d to 2s per lb. in bond.

This large difference between season 1882-83 and 1883-84 is made up in decreased sales during this season of teas sold at 4d to 1s per lb, but this season there is an increase of over 300,000 lb. weight of tea sold by auction over 1s to 2s per lb. as compared with season 1882-3.

Though the sales by auction show this large falling off, this has been made up to a considerable extent by considerable private sales and speculative purchases.

Then it is stated :—

The first four months' imports of China teas are *sans reproche*, and probably the best all round in quality seen here for many years past, but the scarcity of common grades led to injudicious speculation, causing a rise in some instances of fully 50, perhaps 75, per cent. on low qualities ; whilst bringing neglected rubbish to the front, and a large influx of unsalcable and undesirable stock from the other colonies and London. How often have we repeated our warning that, to those who desire them, spurious Tayshans, Macaos, and other akin stuff, are nearly always available to those who wish to deal in them. More especially is this so when the flushing of the tea plant is nearly over, and labor in quantity available and fully employed for a time in re-making up once used, damaged or other rubbish, with stalks, tea seeds, &c., picked out from other tea, but always kept for emergency, instead of being thrown away.

As usual, the Paklums turned out the best in leaf and, in many cases, in liquor, realizing as high as 2s per lb. in bond. Panyongs, with hardly so pretty a leaf or delicate a liquor, rank next, and, in point of usefulness, perhaps first. These two descriptions with perhaps a few Packlings, Soo Moos and Ching Wos, whilst realizing fair prices at the commencement of the season, have ever since been selling at prices that must leave a considerable loss to the importers, and probably the value obtainable by the buyer now and during the last eight months at 1s 0½d to 1s 2d per lb. in bond has been unequalled for years, and it consequently is a length of time since China teas stood so well in the estimation of buyers in the Melbourne market. Kaisows and other medium district teas lost money early in this season, but ever since, with perhapt exception of the last few months, sold beyond their values partly aided by speculation and partly by the requirements of the grocers for a tea at a price to follow up the cheap purchases of 1882-83. So, whilst the month of August saw Paklums, Panyongs, Kenyongs, &c., losing money, it also saw the commencement of the rise in value of Kaisows, which often afterwards culminated in higher prices being paid for these teas than for good sterling samples of other kinds worth intrinsically pence per lb. more. The usual result followed, and all the sweepings of the other markets were poured into us. And the damage does not stop here; for, if our information is correct, undertakings have been given by some of the China houses to lay down teas at a price in Melbourne that will certainly keep the Customs officials busy and we shall probably see the lowest class of China teas on our market this season, 1884-85, that we have had for many years past.

No wonder if, in the face of such a state of things, the demand for Indian teas slackened, good China teas being obtained for low prices and China rubbish for about half what it must have cost to produce and ship it.

POSITION AND PROSPECTS OF BRAZIL.

Sir,—Those who write about Brazil, unfortunately for her, belong to one of two classes—the one that paints her with the most glowing colours, the other that ridicules everything connected with her. Both injure her, albeit it is very easy to avoid these courses by narrating simple facts, which although in some cases they may hurt for a time, as truth often does hurt, cannot fail eventually to benefit her. However, it is to be hoped that in this case *Obsequium amicos veritas odium parit* will not, for once, be verified. How very often Brazil is written of as being "surpassingly fertile!"—Now to suppose a country so generally mountainous as Brazil is, with an area of 3,000,000 square miles, to be of equal fertility, requires an ardent imagination, to say nothing of a great ignorance of geological and physical facts. On the other hand, no one could suppose a country covered with forest, as a large part of Brazil is, a country well-watered in some parts, would not have some rich lands. The chief reason, though, for the belief in the surpassing fertility of the land is not based on what it has been known to give per acre, but rather it is the result of an ocular impression at the sight of the glorious green mountains that form the coast line of the southern half of Brazil. Instinctively, all attribute fertility to forest lands, and to a certain extent this is right, owing to the accumulation of many a century. But there are forests and forests, and some lands are too dry ; and again Brazil is not all covered with dense forests, and even where it is, and where the soil is sufficiently moist and good, the land is not by any means suitable for any other than tropical agriculture. There are myriads of miles of sterile campo land, on which only rank grass grows, and there are miles untold of sandy plains, on which only scrub cork trees and other similar growth will flourish. Brazil is like Europe or the United States, with rich and poor lands, and with the varying gradations between these estates; she has some tracts of coffee lands of the richest soil, red loamy earth 20ft. to 30ft. deep, overlying trap-rock, of which it is a decomposed substance. There are other rich districts among the granite boulders which crop up in so many parts of Brazil, and she has lowlands which have a rich covering of soil brought down to them from the hills during past ages, or are possibly the bottoms of vast lakes whose mud only remains to show their former existence.

It is impossible, though, to treat of Brazil in this manner, for what matters it whether in the valley of the Amazon there are immense tracts of the richest lands, and that in Pará Indian-rubber grows wild, when we are treating of some specific railway or other enterprize one to two thousand miles away? No one thinks of treating Central Asia, India, Australia, or the United States in this way, neither should Brazil be so treated, as there is not a man alive capable of giving a general idea of the country as a whole. Examining the province of São Paulo,

notably one of the richest in Brazil, a territory not much inferior in size to England, Scotland, and Ireland combined, we find that down the coast for a distance of from 50 to 80 miles inland the land is comparatively useless from an agricultural point of view. Beyond this strip of land the soil is a little better, and will, after the forest has been cut or burnt down, produce one or two crops of Indian corn or rice without the need of manuring, after which it is used up. About 100 miles from the sea-coast commences the coffee district, which is also variable in fertility, some parts being very good, others useless from being too dry, and others too sandy. Two hundred miles inland, in the region included between the rivers Pardo, Piracicaba, and Tiete, where trap-rock is chiefly found, is the famous red land (*terra roxa*). Even here there are stretches of miles and miles of sandy campo land, useless for anything. If the European idea of good land—viz., that which with careful tilling and manuring will give good crops—be taken as a standard, then can the whole province of Sao Paulo be considered generally good, for the climate is good, the annual rainfall between 40 and 50 inches on the table land from Sao Paulo inland, and the seasons are well defined. This, however, cannot be called "surpassing fertility." On the contrary, it is the usual hard work of farming. When speaking of "surpassing fertility," then such rich lands as will give crop after crop (of which there are tracts in the province of Sao Paulo) with the *minimum* of labour, and without the necessity of a rotation of crops, is understood. Again, there certainly are good grazing lands in the west of Sao Paulo and in Minas Geraes, hundreds of miles from the markets, but they cannot compare with the prairies of Rio Grande and the Argentine Republic, hence cannot be counted on as a source of railway prosperity for many years to come. Brazil's chief riches are a few tropical products and her unworked minerals. Not having the former to carry, a railroad need not be made, and the carriage of precious metal can be done in a few dozen wagons per year, for the heavier metals for some time to come will not enter the markets. To sum up this question of surpassing fertility, Brazil is very like the United States, in being rich and poor as far as her soil goes, but she cannot compete with the States in many things owing to her physical configuration, her rivers in the southern half of the empire being of little use, having only short stretches of navigable water, and being cut up by innumerable rapids and waterfalls; finally, they chiefly run towards Bolivia and her other western frontiers, instead of towards the coast.

The passenger traffic on nearly all lines in Brazil is carried by one passenger train each way per day, and on some lines this is substituted by a train made up of passengers and goods vehicles mixed, and this is often found to be more than sufficient. Thus it will be seen that the Brazilian railways have very few of the higher forms of development found on European lines.

The *raison d'être* of Brazilian lines is not by any means decided by the wants and necessities of a district, these being too often treated as subordinate to things political, to the convenience of the fortunate owners of a concession carrying with it a general Government guarantee of interest, and to the giving of employment to engineers and contractors.

Some people have tried to see in the Government guaranteed lines the plan of a master-mind to serve the wants of the people and districts through which the lines pass or will pass. To ordinary mortals, though, there is about as much of a plan perceivable as there was archæological significance in the words on the famous stone found by Mr. Pickwick, which proved to be "Bill Stumps his mark." So with the railways. They are chiefly the results of political manœuvres, or are forced on by engineers and contractors. Were it not so, there would be no need to lament the melancholy fact that eight out of ten general Government guarantee lines are almost entirely dependent on the guarantee, and will be so in many cases for a quarter of a century to come. Brazilian railway enterprizes have also another exceedingly hurtful feature, which is, they are cut up into little lines, most of which are under one hundred miles in length, not one being two hundred miles long except the Government Dom Pedro II., which is 450 miles in length. In the province of Sao Paulo there are 850 miles of railway in traffic, which belong to eight separated companies, each with its full set of directors and administrative officers—a thing which helps to keep up high freight charges and prevents many conveniences being given to the public owing to high administrative expenses and other attendant evils.

First on the list of the provincial lines is the Sao Paulo Railway which has paid between 10 and 11 per cent, on its capital besides having repaid to the Government large sums on account of moneys paid at a guarantee of interest during construction and shortly afterwards. This line is only 87 miles long, and, as before said, is exceptionally well situated, for a great part of everything that enters or leaves the province has to pass over its rails. This line, however, only carries about 150,000 passengers and 260,000 tons of goods. The large interest it pays, though, is due to the enormous freight charges, probably among the highest in the world. The following are a few of the authorized Government rates levied on the Sao Paulo and other railways of the province:—Textile and general goods, 11d. per ton per mile; railway iron, ironwork for construction, agricultural implements, iron tubes, &c., 5½d. per ton per mile; coffee, cotton, sugar, 8¼d. per ton per mile; coal, lime, bricks, manure, 1 4-10d. per ton per mile. With such tremendous charges as these it is not a surprizing thing that three of the lines in the province of Sao Paulo pay very high rates of interest, but the question arises whether, with these still in force, it is possible to have any great development in agriculture beyond the growth of one or two such valuable tropical products as coffee and sugar, for what other article of large consumption could bear a freight charge of 8¼d. per ton per mile? Even coffee in the province of Sao Paulo is not planted beyond a limit already reached, as the transport eats up all the profits—in fact, cases have been known during the recent time of low prices of planters not only not receiving anything for their inferior qualities of coffee, but their having to pay the agent a sum over and above the price the coffee realized in the market.

Beyond these generally adopted high charges the Sao Paulo Railway is allowed to charge for 6·87 miles extra on account of the extraordinary work on the Sarra do Mar section of the line, which is worked by wire ropes and fixed engines for five miles. This extra mileage, equal to an increase of 7·9 per cent. on the total length of the line, raises the charges per mile to more than 11¾d on general goods, 8¼d. on coffee, and 1½d. on lime, coal, &c., rates which may be better appreciated by stating that the charge on a ton of coffee from Jundiahy to Santos is about 61s for 87 miles only, whereas steamers take coffee from Santos to Europe, a distance of 5,400 miles, for 30s to 40s, and think themselves well off with 50s a ton. In the foregoing calculations an exchange of 24d per milreis has been followed. Besides the Sao Paulo Railway there are two native companies, the Paulista (an unguaranteed line), and the Mogyana (a provincial guaranteed one), which prolong the Sao Paulo Railway into the interior, and, although having a much less condensed traffic, they pay dividends but slightly inferior to the Sao Paulo Company—a result which is due chiefly to their economical construction. Thus the Paulista, a broad-gauge line 150 miles long, cost only £10,000 per mile, and the Mogyana, a metre-gauge line 190 miles long, only cost £4,000 per mile. A comparison between the cost of these lines and others made with English capital will in part explain why it is that they have paid while the English ones just scrape together enough to defray working expenses, or to pay 1 or 2 per cent. towards the Government guarantee.

The three lines which have thus far paid large dividends have done so because they tap the chief coffee districts and their dividends have gone up or down just as the coffee crop was large or small. Now, should there be a frost, as in the years 1842 and 1869, when the trees for two or three years afterwards did not bear fruit, or should a disease attack the trees as it has done in Ceylon, then would these three lines, the best paying ones in Brazil, find it difficult to pay a 3 or 4 per cent. dividend, seeing that coffee represents 50 to 80 per cent. of their total gross earnings.

Now, if the lines of the province of Sao Paulo are in this state, rich when the crop is large and poor when it is small, what must be the state of those lines in South

Brazil, also with enormous freight charges, which have no coffee to carry, whose agriculture is in an embryonic state and into whose districts emigrants are not steadily flowing? The above facts also prove that even the Sao Paulo lines cannot be considered in a satisfactory state, having as they have but one source of revenue—a state of things that the companies ought to attempt to remedy by making considerable reduction in their freight charges, even though it brought about a reduction of two or more per cent in their dividends for a few years, as after this time the lines would be much more valuable in having more than "one string to their bows."

Taking a general view of the Government guarantees to railways and sugar factories, it will be found that when the lines and factories now being made under guarantee or by the Government itself are completed, Brazil will be responsible for the annual payment of a sum of probably more than £2,000,000 in the form of interest on these two things alone. The prospect of some of the lines paying part of their guaranteed interest is poor indeed, when we find that but two or three are earning anything towards the guarantee, and more especially when the famous Sao Paulo Railway itself is dependent on coffee for more than half its revenue; hence subject any year to a tremendous downfall should either a good hard frost, the leaf disease, or the coffee bug (*Lecanium coffeæ*) appear in the plantations.

There cannot be a doubt that if the present order of things continues, with the annual deficits, the continued construction of lines into sparsely populated districts which at the present time have no agriculture, the granting of guaranteed interest to central sugar factories and other similar undertakings, the Brazilian Government, when the crisis comes for the transformation of slave labour into free, will most surely have to enter into terms with the guaranteed companies for a lower rate of interest, when instead of 6 to 7 per cent, it is possible that only 3 to 4 per cent will be received by the shareholders, with which they will have to be content, it may be for a long period of years.

It must not be supposed that because Brazil is rich in minerals, and has soil suitable for some very valuable tropical product, she will be able to weather the troubles ever attendant on such social diseases as:—

1. A pending emancipation of a million slaves.
2. An ir-redeemable paper currency.
3. Continued annual deficits made up by new loans.

Let those who have their money invested in Brazil look to it; let them set their faces against the raising of money for unnecessary railways and sugar factories, and if they have any spare cash let them offer it as a loan to promote the emancipation of the black man and redemption of the paper currency; then, after these things are resolved, will the country be able to offer employment to capital and give sure and certain guarantee for the payment of large interest, but not till then.—I am, Sir, your obedient servant, WALTER J. HAMMOND.—*London Times.*

AN enterprizing American inventer has patented a process by which he intends to disguise corn, barley, wheat, beans and other amylaceous substances by means of extract of willow bark, till a connoisseur cannot tell the product from real coffee. This would be very hard upon Brazil and Central America, were it likely to succeed. But we have not forgotten the date-coffee enterprize, and the utter failure which attended it.—*British Trade Journal.*

TEA AVERAGES.—We are constantly pointing out how untrustworthy the averages made up by the brokers are, and we have now a very notable proof of this to record. The average for the Glenalla Estate (in circle) was given by Messrs. G. White & Co. as 1s 0¾d, whereas the proprietor has received account sales showing that the real average was 1s 4d. As the sales of Ceylon teas are very closely watched now, and as this was the first shipment from this estate, we think it right to give the matter due prominence.

TEA PICKINGS.

We give a few pickings chiefly from the *Indigo Gazette*, which is rapidly becoming a very valuable repertory of information on all matters connected with tea. A Darjiling correspondent of this paper writes:—"I am sorry to say 'green fly' blight is very prevalent just now on some Terai gardens. This blight is infinitely more destructive than 'red spider.' Strange to say the 'green fly' is said not to have existed in the Terai until very recently—more probably it had not been recognised previously. The heavy rain does not seem to agree with 'red spider' as once the rains set in, he does not appear to spread. Anyhow the flush seems to grow in spite of him." In this connection we may quote from the same paper a paragraph in an essay on "Laying out a Plantation." The writer says:—"A good deal is often said about manuring, red spider, and other blights; but common sense and elbow grease will go a long way towards relieving the planter of his difficulties in both cases. The green jungle growth (*i. e.* the weeds), cut down before it has seeded, and dug well into the land, replenishes it very considerably, and plants raised originally from good healthy seed, and afterwards properly cultivated and kept open to the influences of the atmosphere, carefully pruned and judiciously plucked, are not likely to suffer much from blights and similar troubles. There is much weight in Mr. Schrettky's remarks that 'Sickly parents, as a rule, have sickly offsprings,' and that 'in many cases the diseased state of the tea plant can be traced back to diseased parents.'" The above we believe is the right view of the case. In his introductory remarks this writer observes:—"The tea-plant will *grow* in almost any soil of ordinary fertility, but it thrives best in a rich, brown loam, mixed with decayed vegetable matter, and a little sand to keep it porous. It is not, however, so easily suited as to climate, demanding a very liberal supply of both heat and moisture during the growing season, and being an evergreen its annual necessary period of absolute rest is not a long one. In Ceylon, I believe, hopes are entertained of being able to keep it in a yielding condition almost during the entire year, though with us it seldom puts forth any leaves worth gathering earlier than March or late than November. Both the climate and the soil of the Darjeeling Hills up to an elevation of, say, 5,000 feet, appear to suit it well, except where the land is very steep and exposed to the mid-day sun. Some slopes of this sort even are to be seen fairly well covered with good yielding bushes, but they have not been brought to paying point without a greater expenditure of time and money than suffices for gentler and cooler slopes. When thoroughly established, plants on steep slopes, if the soil is not washed away or otherwise removed from their roots, do best during the wettest seasons, being at such an advantage as to drainage; but the same circumstance, of course, operates terribly against them during the dry weather, and now-a-days Darjeeling gardens are sometimes five or even six months without rain, though twenty years ago, before the forest had been cut away, even *two* months continuous dry weather could scarcely be depended upon." As to the cutting down of the forest influencing the rainfall in the slightest, especially in the hilly country of Darjiling, we defy the writer to give a single figure to prove his case. The forest may and does help to retain

the rain *after it has fallen*, but being itself so very slightly above the earth's surface its presence or absence can have no effect upon the passing clouds. Of a piece with this foolish statement is the following paragraph by the same writer. Treating of "Manufacture" he says:—"But though circulars and memorandums enough to paper scores of factories have been issued, it would be difficult to cull from the whole lot of them even a poor half-dozen really definite or precise rules for guidance in any important detail of manufacture which an intelligent man could confidently and profitably put into practice. If I were to say it is the blind leading the blind I should not be very far wrong." We would warn the writer, who, in spite of this nonsense, knows what he is writing about, that the adoption of the above style of condemning every thing that has ever been written, is not the likely one to secure attention to his own production. We closewith the following notice of a curious law that exists in Darjiling:—

According to a Government notification, thirteen tea grants in this district are to be put up to public auction at the Cutcherry on the 20th proximo for arrears of Government revenue under Section 6, Act XI of 1859. This would be a good chance for what they call in America "speculative causes;" but I fancy the arrears will be paid up long before the date of sale. Planters in this district do not appear to be generally aware of the fact that what is popularly known as the "Sunset Act" is in force in this district, and in consequence of this Act being in force, the proprietor of a grant of land who does not pay up his dues to Government before sunset on the day appointed for payment, is liable to have his grant put up for auction the next day without further notice to him, and if there were no competitors, the property would be sold there and then to anybody who bid up to the amount of revenue due from the estate to Government. This is a matter that proprietors should read, mark and inwardly digest in their own interests. Amongst the list of gardens notified for sale, I observe some very valuable ones that might be got for sums varying from R618 down to R10.

A NEW DEPARTURE IN THE COFFEE PLANT.

We well remember that at first *Hemileia vastatrix* was regarded with comparative indifference, real alarm being felt by experienced planters only when they discovered that, even in cases where grubs could not be suspected of being at work, the trees were sadly deficient in feeding rootlets. That symptom has continued to be as grave as the constant withering of crops of leaves. The intelligence sent us by a correspondent in Maturata, therefore, of the appearance of the normal quantity of feeding rootlets at the bases of the coffee plants, is important and cheering. We hope the change for the better has been observed, and will be confirmed by other planters and in other districts.

A GEORGIA paper tells us that the finest kind of tea has been raised in Houston, Scriven and other counties in Georgia for several years, but no effort has yet been made to prepare it for the market on a commercial scale. The tea plant has proven to be quite hardy in that climate, and very little more trouble to propagate than a persimmon bush, but the difficulties in the way of its preparation have not been yet surmounted. Feasts have been held recently in Bogota and other countries of South America over the discovery that tea could be raised there. Every family in Georgia could easily raise its own tea, and while this has been known for several years but few efforts have been made in that direction,—*Industrial South.*

TEA PICKINGS.

As it is as well to gather as much information as possible concerning a disease at its very commencement, so as to have a good foundation to work upon in any future campaign against it, we admit here a letter we have received from a correspondent accompanying a box containing insects. It is as follows:—

Dear Sir,—By this post I send you in a small match-box several insects I collected yesterday from some black-spotted cacao-pods on an estate. Near the entrance of the estate I found one tree with affected pods, near the centre one, and near the end three trees; on all these trees I found the insects on the sickly pods, but could not find one on any of the good pods on the other trees. Though the pods were all black-spotted, and some nearly all dry and blackish, yet the trees looked healthy. These insects (ant-like), I think, are not the cause, but followers of the disease.

I think you will find the pin spots on coffee leaves and black spots on cacao-pods are both caused by the same insect—a small blue fly. They fly about in swarms, at times make a noise like a humming bee, and are most difficult to catch. You will find them among bees on flowers at times, they fly out from the tree, remain almost like stationary in the air, making a noise like the humming bee, then dart off to another place, and so on.—Yours faithfully,

WATCHMAN.

On opening the box the "humming blue fly" had evidently "darted off to another place" in transit, for he was *non est*. However we sent the remaining contents of the box to our kind referee, and his answeris:—"The ant-like insect is the *Helopeltis Antonii*; another insect (alive) is a small cicada,—not the small blue fly alluded to by 'Watchman.'" The drumstick on the back of these Helopeltes is most marked, and any one having once seen the insect can never again fail to identify it. Yesterday one of our extracts showed that the existence of "Green Fly" had been unheard of in the Terai until lately: and now we find in the "Nilgiri Tea Planter"'s essay that he makes the same assertion concerning the cricket and red spider in southern India. He says:—"A serious enemy to the tea plant, the paddle cricket, does great injuries to young estates in Bengal, by biting them through close to the ground, and another pest, the red spider, causes as serious mischief to the flush in older estates. As they are not present in Southern India, I shall dismiss them without further notice." This essay was written in 1880, and we should like to know whether the assertion still stands good. We very much doubt it, for we know we have the red spider in Ceylon in very considerable numbers, though fortunately they seem as yet to have found our tea too strong for them. If drought is favourable to the development of their ravages, our bushes have certainly been put to a crucial test this year. The superintendent of Abbotsford, has noticed a very large amount of *bug* upon his bushes lately, but beyond the objection of their actual presence upon the leaf, they do not appear to be doing any harm. The leaves have none of that black scale, which is their usual accompaniment on coffee. With regard to this pest the essayist already quoted says:—"I now come to the coffee bug (*Lecanium coffeæ*). I have seen this insect attack isolated bushes here and there on an estate, but chiefly China trees that had exhausted themselves by bearing a heavy crop of seed. I cannot say that I have ever seen it on a healthy hybrid plant." On Abbotsford it is quite the contrary: the bug is most abundant upon the most

luxuriant hybrids. This same writer heads his 'enemies of the tea-plant' with the porcupine. "First and foremost," he says, "among these, from the wholesale havoc that he occasionally makes, stands the Indian porcupine (*Hystrix cristata*). At no period of its existence is the tea-plant safe from his attacks, from the seed put down in the nursery up to the full-grown plants. * * * Their mode of going to work is very systematic ; having fixed upon a good hybrid plant, they commence with the lateral roots close to the stem, cutting them through as cleanly as an axe could do it. They then burrow below these and bite through the tap-root in the same manner. This accomplished, they hoist the tree up, and when it has fallen on its side, leave it. I cannot recollect having seen a single China plant of any size attacked." We have long known how inimical to a vegetable garden porcupines in Ceylon are, but have they yet been found doing damage to our tea? We have heard of wild pigs, in their search after white-grub, upsetting bushes as above described, and rolling huge trees on top of them, but they ought to be looked upon as friends rather than foes, for that white grub does attack tea there is undeniable testimony. The Laird of Mattakelly, with abundance of reason on his side, we admit, holds the opposite view. One of his arguments is that the tea-root is too bitter a morsel for the grub's delicate digestion ; but as a doctor very aptly enquired, "how is it then that he too evidently enjoys our very bitter cinchona roots ?" We only hope that Mr. Smith may be able to demonstrate to us that the exception proves the rule.

LIBERIAN COFFEE PROSPECTS.

At the present moment, the prospects of Liberian coffee in Singapore are singularly good. Strange that this sentence should be penned in the face of an assertion which the writer has heard time and again made that coffee, or if it comes to that, anything worth the cultivation, will not grow in Singapore. But the experiment has been tried, and it has been found that Liberian coffee at all events can be made to grow here, that is with ordinary foresight, watchfulness, and care. M. Chasseriau's charming estate (we use the word charming for it only is applicable to a state of things in which the beauty of nature is enhanced by the efforts of art) now offers evidence as to the success of Liberian coffee cultivation here. Not only has he succeeded marvellously well, but Syed Mahomed Alsagoff also has reaped already large profits from growing this kind of coffee, and what its future will be it would be rash to prophesy. A visit to his estate whereon flourishes the tree will convince more cogently than volumes of description. Now M. Chasseriau having "made an example" of Liberian coffee, and one or two Arab gentlemen having likewise put their hands to the venture and so far succeeded, quite a mania has fallen upon the natives for growing the Liberian berry. Many parcels of seed have been purchased, and several small cultivators in Singapore have abandoned crops on which they formerly relied to plant the hardy Liberian tree, and reap, as a Kling speculator told the writer, a sure and large fortune. It would be scarcely fair to mention small estates that are to be devoted to coffee, on the strength of what has been done by the gentleman referred to in the matter. The fact that the native ear is pricking up at the mention of two things, the appearance of the dreaded *hemileia vastatrix* in Brazil, and the probable rise of Liberian coffee, is sufficiently ominous of the extension of coffee growing here. A financial estimate of the cost of planting Liberian coffee here will not, under these circumstances, be uninteresting. The writer has interviewed M. Chasseriau who has the largest area under coffee cultivation in the island, and whose trees are now thick with fruit, giving an earnest of what the future will bring forth, and has been courteously favoured by that gentleman with a few figures on the subject, which will be of interest and use to those concerned in the industry. Let it be understood that M. Chasseriau has at present 100 acres planted with Liberian coffee, and what a picture of phenomenal prolificness, robustness, and health the trees present? Before the end of 1885, he will have 500 acres planted. So it will be seen that an estimate from him would be based on a comparatively large foundation with the hopes of large results. The figures that he has favoured the writer with are in regard to returns below the expected average, as any one can see who knows the present price, and his computations are carefully worked out. It would be best to give his rough estimates as it was received, so as to avoid the suspicion of misapprehension, and it must be understood that the financial prospectus is made solely with reference to the prospects of Liberian coffee in the Straits, not simply in regard to any picked bit of land. It runs as follows :—

Estimate of the cost of planting one acre of land with Liberian coffee, and of upkeep during the first, second, third, fourth, and fifth, and sixth years.

First, to plant an acre of Liberian coffee on the above estate costs	$ 40
The upkeep for first year	„ 15
do do second year	„ 15
Third year including the gathering and preparing the crop	„ 30
Expenses for fourth year	$ 50
do do fifth year	„ 60
do do sixth year ... ... —	„ 70
	$ 280

Returns.

Third year, one catty per tree on five hundred trees per acre planted at 9¾ feet, by 9¾ feet, say five piculs per acre at $10 per acre	$ 50
Fourth year, three catties per tree which is fifteen piculs per acre, $10	150
Fifth year, four catties per tree, 20 piculs per acre, at $10...	200
Sixth year, five catties per tree, 25 piculs per acre, at $10...	250
	$650
Total Expenses	$280
Net Profit	$370

M. Chasseriau feels confident that, with continued high cultivation during the seventh and eighth years, the yield per tree may be raised from five to eight or more catties per tree. He is now perfectly convinced that our climate and soil are admirably adapted for growing Liberian coffee.—*Straits Times.* [We should judge by this article that *Hemileia vastatrix* has not as yet made its appearance on M. Chasseriau's trees. He is the owner of, we suppose, the largest cassava plantation in the world. He grew coconut-palms for fourteen years along his paths, and then cut them down as utterly unproductive. The peculiar clay soil did not seem suitable for the palm.—ED.]

YEMEN, OR ARABIA FELIX.

(*Extracts from Palgrave's Article "Arabia," in the "Encyclopædia Britannica."*)

The south-eastern coast, extending from Bab-el Mandeb up to Ras-el-Hadd, is not less dreary than that of Hejaz in appearance, and, like it, presents a low and barren mountain range, diversified only by jagged rocks amid

tracts of sand; but it possesses several good harbours—that of Aden in particular, now a British coaling station about 100 miles east of Bab-el-Mandeb; that of Dafar, further up; and that of Keshum; though the two last, owing to the want of traffic with the interior, now serve as mere ports of refuge. Along this shore lie several islands, the largest being that of Mozeyrah, near Ras-el-Hadd, but they are only the haunts of a few half-savage fishermen or are wholly desert.

Following the Red Sea coast down to its southernmost extremity at Aden, we have in view the third great geographical section, that of Yemen. It includes two regions, sea-shore and inland, the former of which is commonly called the "Tehamah." This is a wide strip of coast left by the mountain chain, which continuing on from the Hejaz, runs down as far as Aden, but hereabouts recedes somewhat to the east, thus forming an arc, in the curve of which lies the Tehamah. The mountainous district extends far inland, and gives out several minor branches, some of which reach about three hundred miles to the east.

Yemen, under which name the whole south-western quarter of the peninsula is popularly included, possesses many advantages, both of climate and soil, denied to the greater portion of Arabia. It is a highland country, formed by a labyrinth of precipitous hills and fertile valleys. The air is pure and even cool; the seasons are as regular as those of eastern India, and succeed each other in much the same order. No accurate survey has yet been made to determine the elevation of its mountains, some of which have been roughly, but perhaps incorrectly, estimated at five thousand feet in height; their general direction is from north-west to south-east. The largest plains, or rather plateaus, inclosed by them are that of Nejran on the north, that of Sanaá to the south, and that of Mareb to the east, on the frontier of the great desert. The oasis of the southern Jowf, a basin-like depression occurring in the sandy waste that reaches inland from the high grounds of Yemen up to Oman, on the other side of Arabia, may also be reckoned as belonging to Yemen.

Though the mountains are well supplied with water, no considerable rivers or streams find their way from them to the Red Sea, tropical evaporation combining with the light and porous quality of the soil to dry up the torrent beds; nor do any natural lakes exist, though artificial pools and tanks in which water is preserved all the year round, have been constructed in plenty. Indications of volcanic action, long since extinct, abound throughout Yemen, where basalt formations compose a considerable and the most fertile portion of the coffee-bearing district; in other places jurassic rock predominates, while granite occurs in patches here and there. Spar, agate, onyx, and carnelian are exported from Yemen; silver and gold are reported to have been found on its hills, but on doubtful authority.

It is in this region that Arabian vegetation obtains its most varied, as also its most valuable development. North of Medinah the parched and niggard soil, chiefly composed of marl, flint, and sand, with a supply of rain alike scanty and uncertain, produces little more than varieties of acacia, euphorbias, and thorny shrubs,—a valueless crop. But in the neighbourhood of Medinah commences the great date-palm belt that crosses the peninsula, and extends southward as far as lat. 23° in full vigour. A hundred and more varieties of this tree are said to grow in the immediate vicinity of Medinah alone: the quality of the fruit varies for each kind as also do its size, colour, and flavour. The poorest of all, the "sihanee" date, a yellow, stringy fruit, is much eaten by the Bedouins; the "birnee" is red and succulent; the "jebelee," an upland date, is a staple article of export. Nejd is, however, the favoured land of date-palms: every valley that intersects its vast plateaus waves with them; and the fruit, which often attains a length of two inches with a proportionate thickness, far surpasses the best products of Hejaz in lusciousness as in size. Eaten fresh or stewed with butter, they form the staff of Arab food; and the pulp, after the kernels have been extracted, close-pressed and half dried, is exported under the name of *ajweh* to almost every part of the East. In general a latitude varying from 27° to 22° N., and a sufficient distance from the sea to preclude its atmospheric influences, seem to be the most favourable circumstances for bringing this fruit to perfection; and hence it comes that the produce of the Jowf and of Hareek—which, though inland, lie too far, the one to the north, the other to the south,—of the Hejaz on the Red Sea, and of Rateef on the Persian Gulf coast, is decidedly inferior to that of the inland districts of Kaseem and Nejd. Yet an exception must be made in favour of the "kholas" date, as it is called, that grows in Hasa, and an amber-coloured date of exquisite flavour, the king of dates: the tree itself that bears it is readily distinguished from every other species by the delicacy of its stem and foliage. But in the greater number of instances whatever the variation in the fruit, the palm trees themselves are to an unpractised eye undistinguishable the one from the other.

Besides the date tree, the "doom," a fan-leaved palm bearing a large fibrous and sweetish fruit, is not of uncommon growth in the central and southern districts; while the coconut and betel are planted, though not to such an extent as to reckon among the articles of ordinary cultivation, along the southern and eastern coast. So are also the banana, the papay, and the Indian fig; but all these are of recent importation from the opposite coast of India. Vines are cultivated throughout Arabia, and have been so from time immemorial; and though since the well-known prohibition of the Koran the grapes are no longer pressed for wine, they are in great request as an article of consumption, both fresh and dried. The best fruit is that of Yemen; Oman, where the heat is such that the vintage is gathered in April, comes next both for the quantity and the quality of its produce. In peaches, apricots, pomegranates and oranges, the district of Taif, near Mecca, excels all others. Senna, an article much used by the Arabs in their rough medicine, grows in the southern Hejaz and the Tehamah; so also does the balsam tree, the best of which is indigenous to the district of Safra, near Mecca; its gum is sold even within Arabia itself at a high price. The incense tree, said to be a native of Hadramaut, in the extreme south, has, strange to say, never yet been exactly identified, though its gum is a constant article of export; and the henna tree (*Lawsonia inermis*), used in dyeing, grows abundantly on the western coast. The cotton shrub springs up, seemingly wild, in the gullies of Nejd; but owing to the dryness of the soil and climate, does not repay extensive cultivation. Indigo is grown in many places, chiefly in the low districts bordering on the Persian Gulf.

But although the Arabs themselves consider the date-palm the special pride and ornament of their country a more general verdict would probably be given outside of Arabia itself in favour of the coffee plant. This shrub is by some supposed to be indigenous to Abyssinia; it has, however, for several centuries attained its most extensive distribution and its highest standard of produce in Yemen, where it is cultivated throughout about half of the upland district, the best quality of berry being that which ripens on the western slopes of the mountains in the neighbourhood of Sanaá.

The plant itself is too well-known to require description; it is enough here to remark that its principal flowering season in Yemen is in March. The first crop of the berries ripens in May, a second and a third crop succeed in the course of the year. The diffused atmospheric heat of an equatorial region is requisite for the growth of the coffee plant; yet it needs also a large supply of moisture, and even of shade, to protect it from the too direct action of the sun. In order to obtain these conditions, large trees are often planted here and there among the shrubs, which are arranged on rock terraces one above another, amphitheatre-wise, along the slopes, and are densely crowded together. The processes of gathering and drying the berries, of separating the husks, and of picking the kernels, are all performed by manual labour of the simplest kind. How the drink is prepared has been often and minutely described by travellers; the method employed is tedious, but the result infinitely surpasses that obtained in any other country or by any other method. A slightly acid and very refreshing beverage is also made from an infusion of the "kishr" or outer husk. Its use is almost confined to Yemen; it is esteemed a febrifuge.

A small shrub, called "káat," is common throughout the coffee plantations; it resembles verbena in scent and growth; its leaves are chewed by the natives, much as

those of tobacco are by some Europeans; the effect is that of a gentle stimulant and anti-narcotic. This plant is only found in the south-western regions, and its use is limited to them.

The Pearl Fisheries of Arabia alone add to the commercial riches of the country. They commence at the islands of Bahreyn, which lie immediately off the Arab shore, near the centre of the Persian Gulf, and continue east and south along the district of Katar for a distance of nearly 2,000 miles, after which the banks are lost in deep soundings. The most productive shoals are those between the islands of Halool, and the coast of Katar; the fishing season commences with the spring, and lasts all through the summer. Most of the villages along the coast are wholly inhabited by divers. Arabs and Negroes, who by long practice can remain under water a space of two minutes at a time; the depth they reach does not exceed 15 fathoms, and generally falls much short of it. The oysters are opened on shore, and the pearls carefully sorted and counted by officials stationed for the purpose as a heavy duty equalling 20 per cent of their value, is levied on the spot, though no further dues are taken on exportation. Some of the pearls are of great size and value. The total annual produce is roughly estimated at about £250,000, but probably exceeds that sum; a portion goes to India; another portion up Gulf to Baghdad, whence it is distributed over Syria, Turkey and Persia. The divers themselves are the worst off, as their occupation induces various congestive diseases and premature old age.

Pearls are found, too, in other bivalve shells of these seas and are extensively sold, though at a lower price than those of the oysters. Mother-of-pearl is also common, and is an ordinary article of export, especially to Syria and Egypt, so are also occasionally the corals, and ornamental shells with which these seas abound.

Of the revenues of Arabia it would be difficult to form anything like a correct estimate. Palgrave has stated the yearly receipt of the Nejdean, inclusive of the tribute then (1862) paid into it by Bahreyan and the west of Oman, to be nearly £106,000 sterling—no very large sum.

The revenues of Oman itself, then in a comparatively prosperous condition, are estimated by the same author at nearly ten times the amount, but may possibly have been over-rated by him as those of Yemen were perhaps by Niebuhr. Certainly the general condition of these provinces—the restricted character of the cultivation and the evident poverty (not absolute want, indeed, for that is rare) of the greater number of the inhabitants—do not convey to the visitor the idea of large national wealth or extensive resources. There can, however, be no doubt that both the coast districts of Arabia, in their varied and valuable products, and the central plateau, with its palm-groves, well irrigation, and wide pasture lands, might, under a judicious administration become the sources of much greater revenues, both public and private, than is now the case. The mines, too, in the Metamorphic districts of Yemen and Oman, remain yet to be properly worked. As for the desert proper, which, as we have seen occupies about one-third of the Peninsula, it must, like the ocean of *Childe Harold*, remain what it is to the end of time.

THE CIRCULATION OF SAP.

Although plants have no general circulation like that exhibited in the higher animal life, it is true that each living cell has a circulation interesting in the extreme, when watched through the microscope, as it may be in the leaves of the fresh-water tape grass. Here the sap may be seen to circulate in a steady flow around each cell, carrying with it small particles or green grains. The protoplasm under the cell wall where this movement takes place is a substance having the same composition as the flesh of animals. But these cell walls are not a barrier against the fluids taken up by the roots, which are carried through the stems of the topmost leaves of the loftiest bough; thence, the sap takes a downward movement through the cambium layer and circulates throughout the plant or accumulates wherever a deposit is being laid up for future use. The rise of sap is quite rapid in a leafy and growing plant on a warm dry day, as may be seen from the amount of water it is constantly exhaling from the foliage: this loss is supplied by the absorption of water through the roots, otherwise the plants would die from thirst. The cells of the roots are filled with a much denser substance then the outside moisture, and this moisture is naturally drawn into them. While the leaves are throwing off water, in the form of vapor, there is left behind all the earthy and organic matter; this increases the density of the sap in the cells of the leaf, which draws upon the thinner contents of the cells of the stalk, these upon those below, and thus the action continues down to the roots, which causes a flow from the roots to the leaves. In a somewhat similar way the elaborated sap is attracted toward any growing part, as the bud, and here it is consolidated into fabric or proceeds to the tubes, etc., where it is changed into starch. To make a distinction between elaborated and crude saps, it may be well to remark that the latter is the water absorbed by the roots and carried to the leaves of the plant, while the former is the result of an extensive circulation through the plant's cells.

The wood of growing plants when cut from near the surface has been known to contain nearly 50 per cent of water, and a still greater proportion in young twigs with a living pith has been found. Interesting experiments testing the amount of the flow of sap from different trees have brought to light the fact that the birches yield an immense amount, and an instance is recorded of a paper birch fifteen inches in diameter flowing, in less than two months, 1,486 pounds. It has been supposed that the grape would bleed more freely than any other species of plant, but this is not the case; it really bleeds but little. In regard to tapping sugar maple trees it has been clearly indicated by actual test that the proper method is to insert the spout on the south side as the sap will flow earlier, and more abundantly than on the shaded side, and the late sap is of little value for sugar. It has also been ascertained that an increased number of spouts in a tree will increase the quantity of sap obtained, though it is likely to contain a less amount of sugar. The sap of the sugar maple contains from two to three per cent of sugar while that of the wild grape vine is almost pure water, and it has been found in the late spring to contain no sugar, glucose, or starch. While it is evident that the flow of sap in some plants and trees is dependent upon root absorption, it has been shown that the rise and flow of maple sap is not directly caused by the activity of this absorbent power. There is a much slower movement of sap in the heart of a tree than in sap-wood, which is probably due, in part, to the fact that the old wood is more dense. The sap is separated from the cellulose of the wood by the cold, and under ordinary conditions gradually re-absorbed. The bleeding may be regarded as a sort of leakage from the vessels of the wood, which is probably increased by the elastic force of the gases present.—*Indian Agriculturist.*

MR. J. FERGUSON, of the *Ceylon Observer and Tropical Agriculturist* (whose work on "Ceylon," published by Sampson Low & Co., was recently the subject of favourable notice in our columns), has lately come home on furlough, travelling from Ceylon by way of the Straits Settlements, Hongkong, and Canton in China, Nagasaki, the Inland Sea, Kobé and Yokohama, as well as Tokio in Japan, and thence across the Pacific to America. Mr. Ferguson spent some seven weeks in travelling thorough America, including California, Utah, Kansas, Chicago, Toronto (Canada), and thence through the Eastern and Southern States as far south as Florida, where (as well as in California) sub-tropical agriculture was the subject of observation. At a time when so much interest as to the future of the planting industry, especially in tea, in Ceylon is felt in mercantile and banking circles, it is well to have so good an authority at hand to refer to as this gentleman. A second edition of the standard work, now called "Ceylon in 1884," we see is announced by Sampson Low & Co. Mr. Ferguson returns ere long to his work in Colombo, which city is likely to become the centre for the information to the planters, both of the east and west, through the pages of the *Tropical Agriculturist.—European Mail.*

THE manufacture of perfumeries from Florida-grown flowers bids fair to become an extensive industry in that State. One firm at Jacksonville is already at work. It is reported that a gentleman from South Florida has patented a process for the utilization of the bloom of the mangrove and sapodilla, and to extract the sweet fragrance from the cassava plant as well.

THE TRADE OF ADEN consists chiefly of coals, coffee, cotton goods, dyes, feathers, gums, skins, shells, silks, spices, sugar, and tobacco. The Arabian coffee is known in Aden by the name of *Jebeli* from Jeb, a mountain (a root, traceable in Gibraltar), the plant being grown in the hilly districts of Yemen. Upwards of 7,000 camel loads are brought in yearly to Aden, the export value being something over £300,000, the greater portion going to France. The Somalis prefer Bombay cotton goods to those of Manchester, and pay a higher price for them. This trade is chiefly in the hands of the Parsees. Strangely enough, although indigo grows abundantly in Arabia, it is not manufactured to any extent, the Arabs preferring to import the article from India. The ostrich-feather trade has been valued at about £30,000 a year. The feathers come chiefly from the Somali country. The retail price of a bunch of the very best description of the largest white feathers ought not to be more than R30. The deluded passenger, however, pays much higher prices as a rule to the cork screw-ringleted hawkers. A considerable trade is also carried on in gum, frankincense, and myrrh, as well as in skins of lions, zebras, and monkeys.—*Indian Agriculturist.*

MANILLA.—The following statement of the shipments of the three great staple productions of Manilla—hemp, sugar and coffee—in each of the past six years is from a report by Consul Wilkinson :—

Years.	Hemp. Piculs.	Sugar. Piculs.	Coffee. Piculs.
1883	746,870	3,403 500	128,125
1882	707,344	2,452,000	81,039
1881	868,904	3,362,500	86,682
1880	800,926	2,902,300	84,000
1879	647,959	2,145,000	61,391
1878	667,878	1,890,000	35,782

In 1861, the exports of hemp were only 380,000 piculs, but they steadily increased until 1881, when they reached their highest total of 868,900 piculs. Since 1881 there has been a decline, but the diminution, Consul Wilkinson states, is entirely due to exceptional circumstances, such as outbreak of cholera in the latter half of 1882, which caused a panic amongst the native cultivators, who for a considerable time abstained from all field labour. The increase in the production of sugar is stated to have been even more rapid than that of hemp. In 1861 the shipments barely amounted to 850,000 piculs, while last year they reached a total of 3,404,000 piculs, equal to 212,750 tons. The market value of the hemp exported from Manilla in 1883 was £1,383,700, and that of the sugar, £1,523,300, while the value of the total exports from the whole of the Philippine Islands during the year is estimated at little short of £6,000,000 The export trade of Manilla is at present almost entirely in the hands of British firms, but recently the Government, by imposing a species of income-tax on trading and financial firms, and also by prohibiting the acquisition of any kind of landed property by foreign companies, have been endeavouring to get the trade of the islands more into Spanish hands. This, Consul Wilkinson thinks, is a great mistake, as "it is a well-known fact that the great increase that has taken place within the last thirty years in the trade between these Spanish possessions and Great Britain and the United States is entirely due to British and American capital and enterprise."—*Australasian Trade Review.*

FIBRE MACHINES.—The Government of India proposes to hold a series of experiments of, and trials with, fibre-extracting machines in Calcutta, in September next. These will be in continuation of the trials which were held in February last with the fibre-extracting machines shown at the Calcutta Exhibition; and prizes of considerable value will be offered, though not to the extent of R50,000, as was formerly the case. The trials will be held under the superintendence of Mr. Liotard of the Agricultural Department, and Dr. George King, Superintendent of the Botanical Gardens.—*Madras Mail.*

LEAF-DISEASE IN JAVA is thus noticed in the circular of Messrs. James Cook & Co. :—The Java circulars contain much of interest, and we print the remarks given by friends under date 3rd May, as follows :—"Leaf-disease is reported to have spread over East Java, especially in the Pasourowani, Probolingo, and Bezoekie Residencies, which had not been previously attacked. The coffee trees in these districts are in full bearing; in many plantations, however, all the leaves have disappeared, whilst the branches are loaded with fruit, partly still fresh and green, but gradually blackening and falling off. The disease has now extended all over Central Java, and even seriously affected the Bagelen residencies; so much so that fears are entertained that the year's crop is likely to show a considerable deficiency. Everything is done to prevent the trees from dying out, and to give new force to the plants already injured. Though the official estimate has still been put down under 31st March at 915,950 piculs, it is much to be doubted whether the actual yield will reach over 750 000 piculs. The Menado crop is estimated at 15 250 piculs, and the Government Pedang at 121,400 piculs. According to private advices, however, the latter will barely amount to 100,000 piculs."

A CURE FOR GUMMING IN CUCUMBERS.—I have been a Cucumber grower for years, and, like most others, have at times experienced a good deal of trouble from attacks of gumming. The usual remedies have been resorted to, viz., boring the stem, keeping the stems dry, dusting with dry lime, &c.; but the gumming continued, and the plants eventually died, and I don't remember a single instance in which any of the methods adopted was of any avail. This season I planted two houses in the usual way. For bottom-head I put in about a foot deep of old Mushroom manure, horse-droppings, and shoddy mixed, and the soil used was from an old meadow. The plants set off and got to such a degree of vigour as to excite great hopes of a fine crop; but presently they showed signs of gumming, and several went off, and considerable uneasiness was felt as to the fate of the rest, as several showed unmistakable signs of the dreaded disease. Between hope and desparation, however, I set to work by removing the soil from the stem, and with a pocket-knife scraped off every particle of gum until the stem looked fresh and clean; in some instances the stem was quite half gone. I then got some potting sand and put round the stem, afterwards covering up with some nice fibry soil, taking care that the wounded part was completely covered with the sand and the soil packed up the stem an inch farther. And now as to the result. A week afterwards the stem was examined and found to present a healthy appearance, being covered with white dots, as if new roots were being formed, and a week later proved that such was the case; and now from and above the wounded part roots are being freely formed in the soil, so that I believe the remedy is in my own hands. It would be interesting to your Cucumber growing readers, as well as to myself, to know the result of such treatment as tried by others.—U. J. A. BRUCE, Chorlton-cum-Hardy.—*Gardeners' Chronicle.*

INDIAN AND CEYLON TEA.—The *Morning Post* thus concludes an article quoted by a contemporary:—Those, however, who have once acquired the taste for drinking pure Indian tea never willingly drink any other. At the Health Exhibition it is possible for any one to taste the pure Ceylon tea under the most favorable conditions, and for patriotic considerations, if for no more selfish motive, it is at least worth the while to make the trial.

ONIONS are grown to a large extent in many parts of India, and a most useful and wholesome vegetable they are. It may be as well perhaps if we refer to an experimental cultivation of two plots of land with this product in the United States, feeling no doubt that similar comparative results will be found in this country. On one plot of ground, the soil was well-broken up and pulverized and another plot of similar size was pounded hard with a tolerably heavy rammer. The surface of both plots was covered by finely pulverized soil to the depth of half-an-inch, and three rows on each plot were planted with onion seed. Late planting was disadvantageous to the yield, but the three rows on the compacted soil yielded 9 lb. 7 oz. of merchantable bulbs, while the three rows on the pulverized soil yielded but 3 lb. 3 oz. The percentage of vegetation in the two plots was not noticeably different, although the vegetation was prompter on the compact soil.—*Indian Agriculturist.*

THERE was a grand exhibit at the Calcutta Exhibition of the fibre known as *Sanseviera Zeylanica*, taking as it deserved a first class medal. In the opinion of the jury who reported upon it, there is a great future for this fibre if it can be placed on the market at the figure named, and if it will thrive at the low altitude reported, as in that case it comes within the category of products open to general native cultivation. What is wanted in Bengal is some supplement to jute cultivation, so that in times of depression in this trade, other fibres or products may be reared. The *Sanseviera* is precisely the sort of thing required, for it is cultivable in almost any soil and at a low altitude. Once let the home manufacturer feel that the supply will be ample and continuous, and he will not hesitate to adapt his machinery to the working-up of the fibre just as was the case with jute; but until they are assured of this, we cannot expect spinners at home to take generally to the new fibre.—*Indian Agriculturist.* [The fibre is beautifully fine, but the leaves are short, and the cost of preparation has been hitherto too heavy to allow of profit.—ED.]

THE INSECTS FOUND PREYING ON THE LEAVES OF CACAO IN HAPUTALE are pronounced to be "caterpillars in portable cases of their own construction. They belong to family of moths called *Arctiidæ* or perhaps to the allied genus *Oiketicus.*" Our correspondent cannot say which with certainly. They are curious creatures, resembling the snails in carrying their houses on their back, only those of the caterpillars are frail and temporary. We do not think cultivators need dread these "poochies" much, if the *Helopeltis* keeps away.—Today we have received from the office of the Ceylon Company Limited, a box of the same insects, with the following letter:—"I take the liberty of sending you a small box containing a number of worms or kadis which has been forwarded to me by a gentleman from a low-country estate. He tells me that the worms devour all the succulent leaves of the tea bushes, and, though confined at first to a few small patches, have now spread rapidly over the tea field leaving the trees in some portions perfectly bare of leaf. Information about it will be of much interest." In this case the visitation is serious, and ought to be met by vigorous measures to collect and destroy the worms before they can do mischief and pass into the moth stage.

THE "TROPICAL AGRICULTURIST."—A correspondent writing from Madras, says:—"I am much pleased with the *T. A.* There is some most useful information in it. I have recommended the Madras Railway to take it in for their Libraries."

CEYLON TEA.—Tea seems to be the coming good thing, and wherever coffee has died off, planters are putting down tea; you certainly get delicious tea everywhere in Ceylon, even at the hotels, and I wonder it does not find its way up to Madras; it licks any Indian tea I've ever tasted, even Assam or Kangra, and if you ever tasted it, you'd never drink another drop of the Nilgiri nastiness.—*Cor. of Madras Times.*

COLORING OF COFFEE.—We cannot understand why the State Board of Health does not stop the use of any sort of coloring matter for the coating of coffee. The law defines that an article of food shall be designated adulterated "if it be colored, or coated, or polished, or powdered, whereby damage is concealed, or it is made to appear better than it really is, or of greater value." A strict interpretation of the law would close every mill in the State where coffee is manipulated. As some of the processes for improving the condition are harmless, although illegal, would it not be well to amend the law? Or is it best to stop every avenue to fraud and enforce the law with rigor?—*American Grocer.*

THE SQUARE BAMBOO OF CHINA would be an acquisition in Ceylon. It is thus noticed in the proceedings of the *Agricultural and Horticultural Society of India*:—Dr. MacGowan, corresponding member, sends as a specimen of the ornamental articles manufactured with the square bamboo in China, a plate or tray made of split bamboo neatly fitted together, with an ornamental design pasted or glued on it in relief, the design is in one piece and the full size of the tray, (about 18 inch by 12 inch), and Dr. MacGowan thus describes the process by which the bamboo is made into a sheet of the size required. It is split at one side, soaked in water, spread flat, and heavy weights placed on the top till it is perfectly flat and smooth like a small board. The design is then cut out with a knife and glued to the object to be ornamented. A piece of the flattened bamboo is sent with the tray.

THAT TOBACCO, as ordinarily prepared by some of the manufacturers, is frequently sweetened with molasses, honey, licorice, &c., is not doubted, we think it will be a surprize to most people to learn that a considerable percentage of sugar is a natural constituent of tobacco. Yet, such has been demonstrated to be the fact, by Professor Attfield, F.R.S. Eight samples were obtained from planters in different parts of Virginia, Kentucky and North Carolina, which gave, to 100 parts of leaf, from 5·57 to 9·60 parts of tobacco sugar, and from 8·23 to 12·80 parts of total saccharoid matter. In tobacco grown in unfavorable conditions, or without sufficient heat, the amount of sugar is often but a mere trace, while for light-colored or bright Virginia leaf it will average about 10 per cent.

EVEN in horticulture it seems our American cousins are considerably ahead of the old country; at least the following paragraph in one of our exchanges would lead us to believe so:—"There was recently on exhibition in a store in Dupon-street, San Francisco, a mammoth bunch of grapes from the great grape vine at Santa Barbara. This cluster weighed one hundred and twenty-five pounds and was six feet in circumference and three feet long; the vine from which it was cut is sixteen years old, and produces annually from ten thousand to twelve thousand pounds of grapes. This is probably the largest bunch of grapes ever grown." Undoubtedly it is, as the best on record in England weighed we believe thirty-three pounds, and was exhibited by Mr. T. Roberts before the Royal Botanical Society in 1880.—*Indian Agriculturist.*

HEALTH EXHIBITION.

Banana fruit in splendid bunches, and a meal made from the fruit, was shown by Mr. W. H. Ussher, of Bath. A pamphlet, stating how excellent the food was for a strong man doing heavy work, set us wondering what a railway navvy fed on this substance would do compared with another consuming his beef, pork, bread and beer, and how he would stand in his piece-work account on pay-day. In several stands Paraguay Tea, Ilex paraguayensis, formed one of the exhibits, the renowned restorative being seen in the form of a brownish powder interspersed with coarsely broken up leaf. The Chinese Soya Bean, employed by the Celestials in sauce and oil manufacture, was observed in Mr. Christy's stand, as were Australian Pepper, Piper novæ-hollandiæ. Kokum butter, a substance made from the fruit of Garcinia indica, a tree growing on the hills on the western coast of India. The not very appetising looking balls are prepared by removing the seeds and drying the pulp in the sun. A fuller description of its preparation and uses will be found on p. 320, in this year's volume of the *Gardeners' Chronicle*. Here also were to be seen specimens of Odika bread (Irvingia Barteri) from the region of the Gaboon River, often used in the manufacture of confectionery with chocolate. It is likewise used as a national food by the natives. A variety of Coffee called Maragogipe, that is supplanting the other varieties of Coffee throughout Brazil, and which is said to be exceedingly productive, possessing berries with smooth, satiny skins, and of the highest quality. Erythroxylon coca, the leaves of which make a very delicious liqueur, and contain a very nutritive principle. Several varieties of Cinchonas are to be observed in the form of seeds and bark, such as Calisaya Verde, a Bolivian variety; C. morada, from the same country; C. Ledgeriana, from Ceylon; also a substitute for Cinchona, from Queensland—Alstonia constricta, a genus of the Apocynum family. The Bark is intensely bitter, and is used as a tonic and in stomach complaints. Hymenodictyon excelsum, related to the Cinchonas, with bark that is very astringent, as much as that of Cinchona. This plant is a native of Ceylon, and the bark finds employment in leather tanning. Here were also found Henna, Breadfruit flour, Papaine, a vegetable pepsine, the active principle of Carica papaya; Mandioc, an excellent Sago, a food frequently mentioned by Livingstone in his *Travels on the West Coast of Africa;* Tonquin Beans, the pleasantly perfumed seeds of Dipterix odorata, a native of Cayenne; the seeds are not unlike an almond, but longer, and covered with a shining black skin; Myroxylon Pereiræ, the bark yielding the Balsam of Peru of commerce.—*Gardeners' Chronicle.*

COLONIAL NOTES.

THE OUCHTERLONY VALLEY, SOUTHERN INDIA.—Starting from the Nediwuttum plantations by a bridle path across the intervening grass hills, the top of the Ouchterlony Valley is quickly reached, presenting to the observer a series of views of mountain scenery not to be surpassed anywhere in Southern India. Flanked on the left by the rocky, precipitous heights of the upper Nilgiri plateau, with forest-clad ravines, and gorges down which dash and foam the numerous mountain streams and torrents supplying the Pandi River, which after flowing through a portion of south-east Wynaad, enters the Nellumboor district, so famed for its Teak forests.

To the right it is bounded by a long spur of low fertile hills, the sides of which are covered with flourishing Coffee and Cinchona estates, interspersed with belts of jungle and primæval forests. The bridle path, which runs through the entire length of the valley, is a most interesting ride to any one possessing a botanical turn of mind, a continuous change occurring in the variety of vegetation met with as we descend from an altitude of 5,500 feet above sea level to the lowest point, which is a little over 3,000 feet.

At the commencement the scarlet Rhododendrons form, with the yellow-flowered Hypericum Hookerianum, the principal features of the landscape, the denser jungles having an almost impenetrable undergrowth of a tall-growing Strobilanthus, while most conspicuous amongst the numerous species of Ferns is the magnificent Tree Fern, Alsophila latebrosa. Palms are rare, but species of Dendrocalamus are plentiful in the jungles, the long canes of which are greatly in use for basket-work and tying purposes, and the dwarf Palm, Phœnix farinifera, grows on the open grass lands. The principal grasses, utilised greatly for thatching cattle-sheds and coolie lines, and for protecting the stems of freshly decorticated Cinchona trees, are Andropogon schœnanthus and A. Martinii.

About half a mile down we pass through the Balmadies Coffee and Cinchona Estate, where, although showing signs of being nearly worn out, are some of the finest Cinchona succirubra and officinalis in the district, the Coffee calling for no special remark beyond bearing crops above the average usually attained at a high elevation. A few acres of Tea are also cultivated.

As we pass through the jungle belts we notice specimens of the Nilgiri Nettle, Urtica heterophylla, which yields a fibre of considerable value, a sample of it, forwarded by me to a firm in London, being valued at £60 per ton. Numerous epiphytal Orchids occur on the trees, the principal jungle trees consisting of various species of Diospyros, wild Cinnamon, Artocarpus, Ficus, &c., the most valuable timber trees being Black-wood, White Cedar, Jack, Vengay and Ben Teak.

The Guynd estate, a magnificent property of 800 acres of Coffee in a highly cultivated condition, is next reached. Here large numbers of Cinchonas are planted out amongst the Coffee bushes, great attention being paid to the valuable C. Ledgeriana. The usual crop of coffee is between 200 and 300 tons annually. Three well-built bungalows are on the property, and a fine two-storeyed Coffee store, the pulping-house containing the largest pulping machinery in the district; this is worked by a huge water-wheel, christened "The Viceroy" by Lord Lytton when on a visit to the Ouchterlony Valley during his sojourn in India. Looking round on such flourishing properties one can hardly fancy that not a generation ago nothing was to be seen but dense, dark jungle, through which the wild elephants, bison, and numerous herds of spotted deer and sambur roamed unmolested.

From the adjoining estate, called "Tulloes," there is a fine panoramic view of south-east Wynaad, including the Devallah gold-fields and the distant Vellera Mulla hills, besides numerous outlying Coffee estates and extensive ranges of grass hills.

The jungles here contain fine specimens of Bambusa, including a scandent variety, and an ornamental Asparagus of the same nature, the Oak-leaved Platycerium being also common on the older forest trees, amongst which are to be seen numerous black monkeys, green pigeons, and the pretty Malabar squirrel.

Ipomœa malabarica, the fine purple Cispara creeper, and Gloriosa superba, are some amongst the many flowering plants; a bright scarlet-flowered Ipomœa growing over a granite rock near the Hope Bridge proved also very attractive. Small gardens cultivated by the estate coolies are here and there observed, containing principally Yams, Sweet Potatoes, Castor-oil, and vegetables used in compounding curries, English vegetables being represented by Potatoes, Cabbage, Carrots, Turnips, &c. Various kinds of tropical fruits are more or less plentiful, such as Plantains, Guavas, Limes, Citrons, Oranges, Shaddocks, Jack-fruit, Loquats, Pomegranates and Papaws. The gardens around the planters' bungalows are generally very interesting, furnished with highly-coloured Iresines, Alternantheras, and Coleus, as well as Pelargoniums, Fuchsias, Gardenias, Roses, Crotons, Hibiscus, and others too numerous to mention. Fine hedges are formed with Roses, Lantanas, and Datura sanguinea, and the various species of Thuia thrive remarkably well. All the bungalows on the Ouchterlony property, which is upwards of 50,000 acres in extent, are well built with burnt bricks and sawn timber, the total number of coolies working on the various estates often exceeding 8,000 in number, and altogether over 4,000 acres are already under Coffee cultivation, extension being made annually. Unfortunately this fertile region has lately been the source of much troublesome litigation, owing to the disagreements of the various partners interested therein, in consequence of which it is under the ruling of the High Court of Madras, which conducts all its affairs through the medium of a receiver and manager.—W. F. KEMP.—*Gardeners' Chronicle.*

AGRICULTURE ON THE CONTINENT OF EUROPE.

(Special Letter.)

PARIS, July 19th.

There was no doubt as to the efficacy of the Pasteur discovery of vaccination of stock against the *charbon* disease. Experiments widely conducted on oxen, sheep and pigs, confirmed the value of vaccination as a preservative. But one point remained to be determined. How long did the efficacy of the vaccination last? It was no more permanent in the case of stock than of smallpox with human beings. Roughly, its preservative action was set down at six months. To test the point, the Agricultural Society of Hérault experimented on three races of sheep peculiar to the south of France, of which one, the Larzac, yields the milk from which the famous Roquefort cheese is prepared. Thirty-six sheep were set apart for experiment, and were installed at the Agricultural College of Montpellier. This was in May 1882. In May 1883, six sheep, chosen two by two, from the several breeds, were inoculated with the poisoned virus and resisted its action. In the following November the experiment was effected on another lot of six, same result, immunity. After the lapse of another six months, that is in May 1884, six more animals were similarly treated, and with equally satisfactory results, whilst sheep that had not been vaccinated succumbed. Hence, sheep vaccinated in 1882 resisted the virulent virus in May 1884; that is to say, the immunity was assured for two years.

Professor Heiden of Pommritz has devoted considerable attention to the subject of farmyard manure. He draws attention to the fact, that, while the employment of artificial manures annually augments, and while amelioration takes place in the races of cattle, food has become more concentrated for stock, and farm offices have been improved in construction, but little proportionate attention has been given to the conservation of farmyard manure or to its treatment. In some out-offices, the manure is only removed every week or every month; sometimes longer. The manure is either carted directly to the field or placed in a heap. The Professor inclines to view that the best manure is made by leaving the litter unchanged as long as possible, but on condition that the urine or liquid manure be carefully economized.

Farmyard manure, when neglected, loses the greater part of its soluble matters—now, these are the most precious—and at the same time a notable proportion of nitrogen, under the form of carbonate of ammonia. Farmyard manure consists of excrements, urine, and litter. Urine decomposes the most rapidly; when fresh, the nitrogen exists under the form of urea and hippuric acid; there exists also a small quantity in the ammonia and in the colouring principles of the urine. By the simple absorption of water, the urea is rapidly changed into carbonate of ammonia. The hippuric acid is not slow either in decomposing: urine collected after a space of two days contains none, and in that time it loses about 50 per cent of its nitrogen.

Having a well-constructed liquid manure tank, the Professor urges the employment not the less of gypsum or kainite. And the form in which gypsum ought to be used is as it comes as refuse in the fabrication of superphosphates and phosphates, that is to say, when caprolithes are reduced to powder, acted upon by sulphuric acid and a solution of lime. Now 2 per cent of this gypsum will fix the volatile carbonate of ammonia. From one to three pounds per head of stock per day will suffice. Small farmers, however, ought to take care and not have their sheds too warm, as that would, from a diminution of oxygen in that atmosphere, induce the formation of sulphuret of calcium, which, generating sulphuretted hydrogen gases, would create a bad odour.

In the neighbourhood of Rouen sulphuret of carbon is successfully employed to destroy field-mice. A vessel capable of containing five quarts of the liquid, that which is employed also against the phylloxera, has a cock with a protruding pipe arrangement; the latter is placed at the mouth of the mice-holes, and a simple turn of the cock empties a measured dose of the poison.

I have been informed of a new snaffle combination for stopping bolting horses. This consists of a chain arrangement, which comes into operation the moment the ordinary reins break, or are dropped, and forces two plates in metal-covered leather over the horse's nostrils, besides closing the mouth. The animal, unable to breathe, stops

It is in contemplation to again resume the experiment of cultivating model farms on the *métayage* system, by which pupils would have a share in the profits. This would break them in when they entered on the Association plan on their own account with landed proprietors.

A good deal of wheat is now being imported from India, and more will certainly arrive as the tolls of the Suez Canal are reduced. There is another product that might be studied, that of forage. This is generally insufficient in France, and there is ever a brisk demand for good hay. Half-a-century ago India exported compressed hay to France.

Many of the seed merchants in France present to farm schools samples of new plants, seeds and manures, provided the soil will be specially allocated to the end in view. The farmers in the locality club to pay the rent of a piece of ground, and follow the practical experiments with interest and profit.

Agricultural asylums are to be organized for worn-out labourers; by paying a small sum weekly, a labourer will have the right to food and shelter, at a certain age, with an opportunity to add to his income by moderate work.

The hot summer has developed an enormous number of vipers; their bites are cured by carbolic acid.

Earwigs, so destructive to vegetation, are also numerous; get a flower-pot, place therein a little bran, cover with a slate or tile, put it next a fruit bush or young vegetable; soon the pot will be filled with the insects.

BETWEEN THE POMEROON AND THE ORINOCO.

* * * *

The vegetation of the district, to which we must next turn, has already been described as regards its general characters in distinguishing the parallel tracts of mangrove and mora, which occupy the whole district. But while the mangrove and the mora, respectively, are by far the most abundant plants in these two tracts, other plants are of course intermingled with these, especially in the mora tract. And as these additional plants differ in some degree from those general throughout the colony, they claim a few words of notice.

Next to the mangrove and mora, the most abundant vegetation is supplied by palms of various species. Of these the manicole palm (*Euterpe edulis*) is the most prominent, growing as it does in a profusion greater even than in other parts of British Guiana. It is abundant in the mangrove tract, and is present, though in less abundance, in the mora tract; but it is just where the one of these tracts passes into the other that it flourishes most. On either side of the Biara river, for instance, which runs just where the two tracts meet, it occurs in surprising numbers. Indeed, the dense "bush" there consists almost entirely of enormous numbers of manicoles, varied only by a good many bushes, or rather small trees of 'wild chocolate' (*Pachira aquatica*), of unusually large size, and a few trees of a kind (*Spathelia* sp?) of which more will be said presently.

But if manicole is unusually abundant in the district, another palm, common elsewhere throughout the colony, is here remarkable for its great scarcity. Throughout the district there are but very few kokerite palms (*Maximiliana regia*); and those which do occur are of remarkably stunted growth. Nowhere in this district does one see the noble column-like trunk, the grandly curved capital of huge down-hanging spathes and flowers and fruits, and the noble crown of vast plumed fronds which distinguish the kokerites of other districts. Here, where this palm occurs at all, its dwarfed leaves rise to no great height, it is almost without stem and has its few miserable bunches of flowers and fruit almost buried in the mud.

Yet another palm requires notice here. This is the troolie (*Manicaria saccifera*), which occupies so much of the swamp lands of the Pomeroon and Barima, but is, curiously enough, rare, or at least very locally distributed, in the intermediate, though apparently equally suitable parts. For instance, on the Waini, at least on those parts of its banks immediately above the junction of the Barimanni, the troolie does not occur at all. But on entering the

Moraybo, a tributary it will be remembered of the Waini, close, but on the opposite side to, the Barama, the troolie region is again at once entered; and from there right through to the Barima, and down that river, it is once more abundant. The leaves of this palm being used by the Indians of this district almost exclusively for thatching their houses, those of them who live away from the troolie-swamps have to travel far and to carry home the leaves with much labour.

A few booba-palms *(Iriartea exorrhiza)* are scattered along the upper reaches of the rivers; but apparently nowhere within this district does this palm form the chief vegetation of special tracts of swamp, as is the case in the Corentyn district. The only other palm claiming special notice is a small *Bactris* (like, but not identical with, *B. leptocarpa* of Professor Trail), called by the Warraus of this district *yarooa*, which occurs in very great abundance on the lower part of the Barama, from its mouth for some distance upward, and occurs scantily in one or two spots on the upper Waini.

Along the upper reaches of these rivers two flowering trees form a special and very noticeable feature. One of these is the beautiful *Brownea racemosa*, the 'rose of the tropics' as Richard Schomburgk characteristically, but somewhat inaptly, called it. It occurs scantily on the Pomeroon, but apparently nowhere in Guiana south of that. But on the Waini, the Barama, the Barima and their tributaries this tree, for it there attains the dimensions of a small tree, constitutes the bulk of the lower growth under the moras. Though it appears not to flower abundantly, its few but very large bunches of blossoms are of such intensely brilliant crimson colour as to attract the eye from afar. Equally attractive are the enormous magnolia-like flowers of a *Gustavia*, which is very abundant on these rivers.

One other three, though occurring throughout Guiana, is nowhere so abundant as here. This is a species of *Spathelia*, which makes a great show among the moras by the river banks. In a young state its single upright stem and palm-like crown of grandly cut, dark-green leaves make it look like a young booba-palm; but as it grows older, it branches scantily, and forms a widespreading head of a few finely-grouped leaf-clusters, in the midst of each of which is set, in the flowering season, a huge plume of countless white flowers.

Of the prickly bamboo which seems to belong, as regards Guiana, almost exclusively to this district, I have written already in an earlier number of *Timehri*.

Orchids, as might be expected from the damp character of the district, are unusually abundant; but these are not very different from those of other parts of Guiana. Probably because the district has been less visited and less despoiled than many others, several orchids, however, which were apparently once abundant throughout the colony but are now rare elsewhere, are here abundant. As an example of this kind, may be mentioned *Oncidium Lanceanum*, which, common as it is in quasi-cultivation in the gardens of the coast, is now rarely to be seen in a wild state, except in this district, in which it is fairly abundant.

One very beautiful little yellow orchid *(Oncidium iridifolium)*, occurring sparingly and in very small clumps on the Pomeroon, grows wonderfully abundantly and in very much larger clumps on the Barima. The plant is fan-shaped, like a tiny iris plant, generally not more than an inch high and as much across, from which rises, well above the leaves, a delicate stem, on which unfold, one at a time, many yellow flowers. Generally, each plant consists of one, or at most two, fan-like tufts of leaves; but on the Barima plants are to be found composed of a dozen or more tufts, but so small that one can hold the whole clump, root and leaves, in the hollow of both hands; and yet there may be on it, besides buds, from thirty to forty open flowers each an inch long and three quarters of an inch across, of brilliant yellow, and like, but of more brilliant tint than single florets of *Oncidium altissimum*.

Another peculiar, and somewhat puzzling, orchid occurs in this district, resembling in the general habit of plant and leaf (though these latter are broader and of a darker shade) *Burlingtonia candida*, but with a pendent wreath of greenish white flowers, like a long, downhanging spike of mignonette, rather the wild English mignonette than the sweet kind of gardens.

A beautiful pure yellow (lemon coloured) variety of *Gongora* is also noteworthy; a violet flowered *Sobralia* grows, though sparingly, on some of the tree trunks; and in the shady creeks, the lovely *Stanhopea grandiflora* hangs down many of its great white delicate flowers.

On the whole, it may safely be affirmed that while the vegetation of this district resembles in the main that of the rest of Guiana, yet it has certain well-marked and noteworthy features.

* * * *

And this brings up the subject of the products of the district. At present these are extremely few and unimportant. Chief of those actually obtained is perhaps balata, the milk of the bullet-tree *(Mimusops balata)*, which till recently was abundantly and widely scattered throughout the mora tract; but, owing to this same search for balata and the wasteful method in which it has been carried on, the tree is now not far from being exterminated. Almost every Indian collects bullet tree milk, and in doing so unfortunately chops down the trees. Considerable quantities of locust gum are also collected by the Indians; but as is the case with this substance elsewhere in the colony, the supply, by its very nature, is limited, and it must before long be virtually exhausted, even under the very dilatory and inefficient system of collection followed by the Indians. By the Indians a few yams are grown for purposes of barter, and a few fowls and parrots reared; and a very large quantity of fish is caught, cured, and, with the corresponding amount of fish-glue, bartered. And, considering the small amount of land under such cultivation, large quantities of yams, corn, and even cacao are produced by the few coloured and Portuguese residents; this produce finding its way in about equal proportions into the English colony and into Venezuela. A very little timber, chiefly red cedar, is also cut by these people. This fairly exhausts the list of produce at present obtained from the district.

As to produce which might be obtained, the land is very rich, and, under proper cultivation and with the necessary heavy outlay on drainage, might undoubtedly be made as fruitful as the similar lands along that part of the coast which lies between the Essequibo and the Corentyn; and the uplands of the district seem especially suited for the cultivation of coffee and cacao. Timber is abundant and fine; the mora, especially on the upper parts of the rivers, is far finer than any to be found elsewhere in the colony. And up the Barima and Amakooroo red cedar is very abundant and fine. Nor would there be much difficulty in getting this timber, when once cut, to market; for the rivers are large and fine and afford an unsurpassed system of water carriage. Lastly—and according to some this is the most important fact about the district—it may be taken almost for granted that gold will, for good or evil, one day be found there.—*Journal of the Royal Agricultural and Commercial Society of British Guiana.*

CAPTAIN LILJEBLAD, of the L.M.S., schooner Ellangowan, has brought over four new varieties of sugar-cane from South Cape (says the *Cooktown Courier*). These he has handed to Mr. F. Bauer, who thinks very highly of two of these varieties, and intends to plant them at the Bloomfield. Too much credit cannot be given to Captain Liljeblad for thus introducing New Guinea product-yielding plants. The betel palm would be well worth cultivating here, and should thrive admirably.—*Queenslander.*

UTILISATION OF MAIZE HUSKS.—The husks of maize, or Indian corn, after the grain has been extracted, serve only for manure, or, in some cases, as fuel for portable engines for agricultural purposes. But they contain starch, albumen, and other substances capable of being turned to account, and even afford an alcohol which is at least equal to potato spirit, leaving a pulp suitable for the food of various animals. Herr Holl, of Worms, has invented a process for utilising these husks, by which he exposes the husks for an hour or an hour and a-half to the action of steam, at a pressure of 35 to 45 lb. per square inch, in order to reduce them to powder, and thus open the starch cells, when distillation is proceeded with in the ordinary manner.—*Journal of the Society of Arts.*

COCOA AND CHOCOLATE.

I.—Cocoa.

We purpose to give an elaborate article on cocoa culture, derived from sources which may well be reckoned among the very best. With this we do not mean to assert that other sources may not furnish very important and valuable informations on the subject, though they may be of a less comprehensive description.

Among these an article deserves to be mentioned of the celebrated Boussingault, who gives us many very interesting particulars about the cocoa. With these particulars we will preface our article, by giving them intact.

"The cocoa-tree is generally known in the tropical parts of America; when it first became known, it was only cultivated in Mexico, and more especially where the natives were the original Toltecs and Astecs, namely in Guatemala and Nicaragua.

In the reign of Montezuma, the Spaniards transported the tree to the Canary Islands, to Venezuela and to the Antilles.

The cocoa-tree demands a rich, deep and humid soil; nothing suits better than cleared forest-land. All the plantations have the same aspect; they are spots protected from wind, at a short distance from the sea, or on the banks of rivers.

When a plot of ground is judged fit for the culture, the first care is to provide for shade. If the ground has to be cleared, the trees that are in bloom are allowed to stand, or else plants of rapid growth are set, such as bananas (*Erythrina Umbrosa*).

South of the equator, in the Province of Guayaquil, the seeds are immediately planted, while in Venezuela the seeds are first made to germinate in nurseries, taking all possible care to protect the young plant from the heat of the sun's rays. The seed germinates in eight or ten days. When two years old, the cocoa-tree has attained a height of one metre; at that period it is topped. The tree blooms generally at the age of two years and a half, in a favourable climate, viz., where the temperature is 27 à 29 degrees Celsius.

There are few plants the blossoms of which are so small, especially as compared with the volume of the fruit, as the cocoa-tree. A bud measured by me when it was just blown, proved to be no larger than four millimetres, in diameter. The corona bore ten silvery leaflets, ranged round five pistils.

The blossoms are not isolated but in clusters, immediately on the stem and at all heights, also on the parent-branches, even on the ligneous roots sticking out a little above the surface of the ground.

Between the fall of the blossoms and the period of maturity of the fruit a space of four months elapses. The fruit, commonly called *cabasses*, is divided into four lobes; the weight varies between 300 and 500 grammes. The pips or beans are taken out and dried in the sun; at night they are shaken out in heaps under a shed. Very soon they begin to ferment, which might become injurious if allowed to continue. From 100 kilogr. of kernels Boussingault has seen as much as 45 à 50 kilogr. of dry cocoa won in a *hacienda* (plantation), fit for commerce. A cocoa-tree, seven or eight years old, furnishes yearly on an average 0·75 kilogr. of dry cocoa. At Gigante, in the elevated regions of Magdalena, the yield is greater, being there 2 kilograms.

The cocoa-beans are peeled by the action of a moderate heat; the husk then becomes brittle and is removed by a winnowing apparatus. By roasting, the bean obtains, like the coffee-bean, an aroma, arising from a small proportion of a volatile principle; this is the aroma that distinguishes the chocolate.

The cocoa-beans are rich in nourishing matter. Besides a large proportion of fatty matter, they contain an azotic substance, agreeing with *albumen* and *caseine*, as also *theobromine* and other matter. These constituents, however, vary as to quantity, according to the habitat. All this appears from numerous analyses, made in the *Conservatoire des Arts et Métiers*, and elsewhere. One of the results of such an analysis, made of a species of cocoa from Trinidad, is as follows:—Butter, gluten, theobromine, asparagine, a species of gum yielding mucic acid, free and combined tartaric acid, soluble cellulose, ash, and some undefinable matters.

The peeled cocoa bean after roasting is known to be the basis of chocolate. The French chocolates contain 55 à 59 per cent of sugar, the Spanish only 40 à 53 per cent.

The genuine, unsophisticated chocolate consists only of cocoa and sugar; the latter substance added in too great quantity would deteriorate the quality. When Boussingault had to undertake a distant expedition in America, he took with him a provision of chocolate which he purposely prepared of 80 parts of cocoa and 20 parts of sugar, which compound agreed with

Sugar	20	parts.
Butter	41	„
Albumen	10	„
Phosphates	3	„
Other matters	26	„

This chocolate formed for his purpose a useful addition to the allotments of dried flesh (*tasajo*) and biscuit of maize and cassave-cakes.

The Mexicans made of cocoa, sugar and a little maize meal a dough, which they called chocolate.

Up to the sixteenth century travellers differed considerably in their opinions about chocolate. Acosta condemned it; Fernando Cortez on the other hand exaggerated its virtues, by affirming that on taking one cup of the beverage in the morning, you could march the whole day long without taking any other nourishment. In France, too, the new beverage had its advocates and detractors. Madame de Sévigné writing to her daughter says:—

"I was desirous of becoming reconciled to chocolate; the day before yesterday I took some after dinner as a digestive, to be able to sup well in the evening, and I took some yesterday too as a nourishment, to be able to fast till the evening; all resulted to my desire, and therefore I now find chocolate a good thing, for you can do with it what you like."

So much is certain, that chocolate contains in a small volume a great quantity of nourishment. Humboldt reminding that it has been rightly said that in Africa rice, gum and the butter of Shea enables a man to cross the desert, adds the observation that, in the new world, he was enabled to ascend the high mountain-plains of the Andes, and cross the vast forests by the use of chocolate and maize meal.

In consequence of the combination of albumen, fat, sugary substances and phosphates, the cocoa reminds us of the composition of milk, the beverage, according to Prout, that is the type of every nourishing principle.

As soon as man attains a certain degree of civilization, he often adds to his food plants that effect his organism like fermented liquors. Like wine used in moderation these matters act beneficially on the digestion; they stimulate the memory, invigorate the imagination, and excite a feeling of well-being, without inducing that uncomfortable reaction, which is but too often the consequence of the abuse of alcoholic drinks.

It is an interesting fact that the various races of men, even those most remote from each other, and having never been in communication or relation with each other, have prepared stimulants from certain vegetable productions. In China it is tea, in Arabia coffee, in Peru coca, in Paraguay maize, in Mexico cocoa, etc. Some use the leaves, others the fruit, beans, pips or kernels of plants that have no resemblance whatever with each other —at least in a botanical sense—and yet all these beverages, notwithstanding the difference of derivation and qualities, act in the same way on the nervous system and the digestion. The cause of this must be explained by all these various plants' possessing certain substances that have the constituents of alkaloids and like properties; in coffee it is the *cafeine*, in tea and burnt maize, the *theine*; in cocoa, it is the *theobromine*, in the coca leaves it is the *cocaïne*. So the Chinese, the Arabs, the Peruvians, the Indians of Paraguay, the Incas, the Astecs were all under the influence of the same active principle when they used their customary beverages.

The *cacao*, called by the English *cocoa*, is the fruit of a tree *Theobroma cacao*. Other trees belonging to the order *Buttneriaceae*, as *Theobroma tricolor*, *Th. Speciosum*, *Th. Sylvestre*, *Th. Subincanum*, etc., also yield a similar fruit.

The cocoa-tree proper is a native of the tropical region

of America and most probably derived from Mexico. Its height varies from 15 to 40 feet, but when under cultivation seldom exceeds 18 feet in height. It is at present cultivated in almost all tropical countries.

The wood of this tree is light and porous, and takes a beautiful polish. The leaves are fully one foot in length, at first of a purple colour, afterwards green. The sepals are pink, the petals of a deep yellow.

In the tropics it grows on eminences as high as 2,000 feet, occurs wild between 17 degrees latitude north and south, but is cultivated in both directions up to 25° N. and S. latitude.

The seeds or beans are contained within an egg-shaped oblong gourd, of a dirty lemon colour, with a reddish brown ring 6 or 8 inches long and 3 or 3½ inches thick; this fruit has a ligneous shell, pentagonal, and contains a white, rather sweet-tasted pasty matter, in which the seeds are embedded. In each of the five angles are mostly eight seeds lying close together, placed in rows, of a yellowish brown colour. These seeds are at most one inch long, and surrounded by a brittle, thin, scaly shell; they taste rather bitter and astringent. The tree is constantly in bloom, like the lemon tree, the coffee tree and others, thus bearing blossoms and fruit at the same time. To give the seeds or beans a pleasanter taste, to destroy the germ and to dry them, they are treated in three principal ways, which we will describe further on more in detail.

The value of the different sorts for commerce depends on the various ways of treatment, and also on circumstances resulting from climate and culture.

These sorts are generally named after the countries where they grow, or the ports whence they are exported.

The cocoa-plantations yield annually two harvests; one of these occurs in the months from February to June, while the other takes place in the months from August to December. The second harvest yields the largest crop.

After the fruit are plucked, they are opened, and the sweetish acid, pasty pulp, mentioned above is removed, and the seed or beans are taken out. These seeds are then treated after one of the following methods:—

I.—The seeds are shaken in heaps, often stirred and then left to dry in the sun.

II.—The seeds are put into tubs, and the covers pressed down upon them by the weight of stones; then a gentle ferment takes place.

III.—The seeds are thrown into pits dug in the ground, are then covered up with loose earth, and afterwards spread out on a sandy ground to dry in the sun. Here also a gentle fermentation, mostly called rotting, takes place, by which the germs are destroyed and the beans themselves rendered more durable.

Many give the preference to the second method, because, according to them, the taste is less bitter, and the bean browner and harder.

The best sorts of cocoa are the Mexican, but these are not all brought in the trade, since the Mexicans keep the best for their own use.

A.—Clayed Sorts.

The good sorts in commerce are:—

I.—*Cacao soconusco*, or *Cacao soconuzco*; the bean of this sort is small and very convex; it has a fine aromatic fragrance and a delicate flavour. The colour is golden-yellow. It grows in Mexico, and its scientific name is *Theobroma ovalifolia*.

II.—*Cacao esmeralda*, the bean of which is still smaller. This species grows chiefly in Peru and Ecuador. The scientific name is *Theobroma microcarpa*.

III.—*Caraccas cacao*, called also *Cacao de la Guayra*, with pretty large thick seeds. This sort possesses an agreeable aroma, while the taste is spicy and rather oily and bitter.

IV.—*Guatemala Cacao*, with very large, thick, strongly vaulted, sometimes angular seeds. It grows in Central America, and with a number of other sorts bears the common appellation of *Theobroma Cacao* or *Theobroma Sativa*.

V.—*Guayaquil Cocoa*, a sort very nearly approaching the Caraccas. It grows in Ecuador and Peru, and bears with the Esmeralda sort the botanical name of *Theobroma microcarpa*.

VI.—*Guyana Cocoa*, by which name the various sorts of Berbice, Surinam and Essequebo are distinguished. The botanical name is *Theobroma Guayanensis*. It grows in Cayenne, Surinam and elsewhere. The beans of this sort are commonly covered with a grey or reddish clay, in which appear small glittering scales.

B.—Unclayed Sorts.

I.—*Cayenne Cocoa*, with unequal seeds, partially of a dark-red colour and hard, partially ash-coloured, very brittle, inside bluish-red.

II.—*Cocoa of the Islands.*—This sort is mainly cultivated in the West Indies, in the Antilles. The seeds are not large, flat, and pointy at one end, blunt at the other, of a reddish brown colour, and of an astringent and bitter taste.

III.—*Brazilian Cocoa.*—To this species belong:—

a.—The *Para*, the botanical name of which is *Theobroma speciosa*; it grows in Brazil.

b.—The *Marahan*, the botanical name of which is *Theobroma bicolor*, while the name under which it is known in commerce is *Bahia*. It grows likewise in Brazil.

c.—The *Rio-Negro*, like the other two sorts growing in Brazil, and agreeing with the other Brazilian sorts of cocoa in its beans being small, flat and smooth, of a reddish or yellowish brown colour and a bitter and astringent taste.

In the seeds we distinguish the shell and the kernel. The principal substance of the beans is a fatty oil, the proportion of which in some sorts is above 50 per cent. They further contain albumen, starch, and an indifferent, crystalizable, white substance called *Theobromine*.

According to analyses of several scientists, the shell is on an average 12 per cent and the kernel 88 per cent of the weight of the beans. A careful analysis of the kernel of a good Esmeralda sort presented the following results:—

Fat (cocoa-butter)	...	53·10 per cent.
Cocoa-red	...	2·01 „
Starch	...	10·91 „
Gums	...	7·75 „
Albumen	...	16·70 „
Vegetable Fibre	...	0·90 „
Water	...	5·28 „
Ashes	...	1·99 „

From the following figures stating the annual produce of the countries named, the general importance of the culture may be somewhat judged of:—

Ecuador	14,000,000 kilograms.
Trinidad	5,500,000 „
Brazil	3,500,000 „
Venezuela	3,000,000 „
Grenada	1,000,000 „
Mexico	1,000,000 „
Martinique	350,000 „
St. Vincent and Hayti	275,000 „
Celebes	125,000 „
St. Lucia	125,000 „
Guadalope	100,000 „
Dominica	100,000 „
Cayenne	33,000 „
Jamaica	25,000 „

The climatic conditions of some regions render certain modifications in the culture necessary.

The first care of the cocoa-planter is to lay out a nursery for the young plants. For this purpose a plot of humid ground is selected, especially free from weeds. The cocoa seeds are taken carefully from the ripe pods; they are sown at intervals of one foot in furrows of two inches depth, and then covered lightly with earth. Then the banana leaves are spread over the ground, and are left for about two weeks; at the end of this period the cocoa-plants begin to appear. The ground must be carefully watched as to weeds, and these must be carefully extracted till the young plants have attained a height of 12 to 18 in., then they are carefully dug up and transplanted to the plantation proper.

The ground to be chosen for this purpose must be a rich fat soil, and in a fit situation for irrigation. The trees grow best on gentle slopes, protected against the prevailing cold winds. When the ground is previously well prepared, seeds or shoots of varieties of the coral-trees (*Erythrina Coralodendron*) are planted at intervals of 25 to 40 feet; these are called here, as elsewhere, *shades* or *madre di cacao*; they grow up luxuriously, and yield constantly the shade required for the cocoa.

When this is effected then the young cocoa-plants are committed to the ground in straight lines, about 12 to 30 feet asunder; the difference in the intervals depends on the nature of the ground, the climate, and the nature of the plant under culture.

As the coral trees do not yield immediately sufficient shade, coffee, bananas and manioc are placed between the cocoa-plants; they then grow up together till the coral trees have grown sufficiently to give the necessary shade; then the bananas and manioks are removed, while the coffee plants are left standing.

In the second year the cocoa-tree begins to blossom, but these blossoms must be nipped off; in the third year they require more air, so the coffee shrubs are also removed.

One of the most important things in the culture is the due pruning of the cocoa-trees, to get as straight and clean a stem as possible, bearing a well-shaped tuft. Then care must be taken to remove all weeds. The weeding must not be done with a hoe, but with a sort of shovel or spade.

Sometimes the tree is attacked by a malady, which is called *mancha*; this first attacks the roots, and then it rapidly causes death; the disease spreads so rapidly in a plantation, that thousands of trees are frequently destroyed in one night.

Besides this disease, the tree is also infested by various insects. Even the seeds laid out in the nurseries are often destroyed by rats and other vermin. The young plants often suffer from a kind of insect called Koti-Kotis, which proceed from a caterpillar. In fig. 4 this caterpillar, the pupa and the kind of beetle that proceeds from it, are represented, while fig. 2 and 5 show another kind of insects, greatly magnified, that infest this plant. These, as well as a kind of ant, bore holes in the bark, nestle themselves under the bark and gnaw into it, while the ants devour the leaves. The caterpillar, represented in fig. 4 penetrates also into the fruit, and devours the beans. Hence it often happens that before maturity they turn black and rot. Mr. Van Gorkom in his *Oost Indische Cultures*," vol. II., p. 478, says what follows on this subject:—

"From the latest Government reports, it appears that the culture in the Moluccas has suffered much from a disease which we observed frequently also in West Java. The fruit turn black before maturity and rot. All kinds of remedies have been tried, but without any observable favourable result. Some pretend that the disease abates if the bark of the trees is thoroughly notched. Experienced planters are of opinion that the disease mostly manifests itself when a long drought is succeeded by much wet weather."

And on page 479 he says:—"In general climates the cocoa may be treated in the same way as coffee; it is in the very same relation with regard to shade and wind, but it requires two or three times more growing space. In America, too, this culture has to struggle with various diseases and plagues, which are also probably the consequences of a want of proper care. If a systematic clearing and pruning and proper draining etc. were more attended to, there would probably be less cause of complaint."

Besides these things one of the greatest plagues of the culture is *the wind*. Whole plantations are often destroyed by a single storm.

The harvest generally takes place, as we have already said, about June and December. For this reason we speak of the *Midsummer Crop* and the *Christmas Crop*. These periods apply chiefly to those parts that are situated in higher or lower latitudes than the Tropics. Within the Tropics the fruit ripen all the year round, therefore the trees are watched every fortnight, in order to gather the ripe fruit and at the same time to prune where it is necessary. To reach perfect maturity, the fruit requires five months; but since the tree flourishes all the year round, this explains the possibility of a fortnightly crop.

At the age of three or four years the young trees begin already to bear fruit, though small and few. Not till their eighth or tenth year do they become very productive, and so they remain for 15 to 35 or 40 years.

The harvesting itself requires much care. Men, women and children are employed in it. The fruit to be plucked are culled with care, *i.e.*, only those that are perfectly ripe. Unripe or over-ripe fruit give a much inferior yield. The best way to ascertain whether the fruit is ripe, is to observe the sound it yields on tapping; the ripe fruit then sound hollow, as the seeds or beans have then detached themselves from the pod. The ripe fruit can also be distinguished from the unripe by their colour.

The low-hanging fruit are wrenched off, those hanging higher are cut off with a kind of pruning hook, as represented in fig. 3 and 6. Care must be taken not to damage the branches. Women and children pick up the fruit thus gathered and carry them to the store-room or work-shops, where they undergo the necessary treatment.

Regarding the produce of the culture writers differ considerably. We, for our part, ascribe this chiefly to their taking account of trees in different localities.

We will confine ourselves to the two following statements, the first of which is taken from the work mentioned above of Mr. Van Gorkom, p. 479, while the other is from the admirable work of Charles G. Warnford Lock, entitled Spon's *Encyclopaedia of the Industrial Arts, Manufacturers, and Raw Commercial Products*, vol. I., p. 686. Van Gorkom says:—"What the reliable produce per tree can be, is difficult to say with any certainty; one year differs considerably from another, and also several individuals in one and the same plantation are far from being of equal value. According to Mr. Van Eijbergen of the East India C. S. who has described the cocoa culture, it occurs that single trees produce 300 à 400 fruit; on an average, however, one must not reckon on more than a score of fruit per annum. About thirty full-grown fruit would yield one kilo of *dry* beans. The drying of the fresh kernels or beans causes a loss in weight of 40 or 50 per cent.

The other authority mentioned above, whom we have consulted, says as follows:—"Only in very particular cases is it allowable to plant more than 900 trees on one acre of land. The average annual produce is estimated at 4 or 6 lb. from each ripe plant, though there are also instances mentioned of a produce of 11 lb. from one tree in one season, and even of 15 to 18 and 20 lb. from sundry single trees."

On comparing these two statements carefully, we shall see that they do not diverge considerably. For according to Van Gorkom, one tree would yield on an average 1 kilo of dry beans, and according to Warnford Lock 2 or 3 kilos of fresh beans, which according to Van Eijbergen lose 40 or 50 per cent of their weight in drying, so that the latter authority agrees, as to produce, pretty well with Van Gorkom.

In the English work mentioned, the portion that treats of the produce ends with the following observation:—"The culture of cocoa is considered profitable for great capitalists, because it requires less outlay and labour, and yields more than perhaps any other tropical culture, but the dangers of storms and the ravages of insects do render it somewhat risky.

As regards the costs of the culture, the general rule holds that, on an average, 15 à 20 labourers are required for every 30,000 or 40,000 trees, making a yearly outlay of 2,400 à 3,000 guilders, so on an average one hundred guilders per 1.000 trees.

In the first part of our article we mentioned the fermentationprocess, to which the beans are subjected after gathering. We deem it necessary to return to the subject more in detail.

In Surinam, and elsewhere in America, the fruit is broken open immediately after gathering; then there flows from it a juice that is carefully caught up in bottles, to be used afterwards as a refreshing beverage. It is a little acrid but not unpleasant. If diluted with water and allowed to stand some time, a fermentation takes place in the fluid, which converts it into a fragrant vinegar. To the natives of West India this juice as well as the vinegar is a delicacy. The fruits which grow in the tropics of the old world possess no such juice, or at any rate so little that it is not considered worth while to collect it. The fruit is there simply cut open with a wooden knife, we should almost say with a folding stick, or else it is carefully broken with a hammer.

In either case the great object is the beans, which are then subjected to one of the treatments mentioned above, in order to effect the fermentation process upon the beans; yet this process must not be continued too far, for then there is the risk of the beans turning

* We regret we cannot reproduce these figures.—ED.

black instead of a dull reddish brown. By the fermentation, which seems indispensable, the slimy and sugary pod loosens, the colour changes, and the smell undergoes a modification. Without this process the bean tastes acrid, nay even sour.

For exportation to Europe, the second of the formerly mentioned fermentation methods is practised; namely, the beans are shaken into vessels the covers of which are weighted with stones, and these are put in a closed apartment exposed to the sun's rays. In this room, usually called the *sweating room*, the beans are left for a comparatively short time, 3 or 4 days, exposed to the temperature of 60° Celsius (=140° F.); they hereby lose a good deal of water along with the acrid, astringent principle, become, of course, lighter, acquire a sweet agreeable smell and flavour and a cinnamon colour, while the skin is easily detached. The fluid, which they exude, is thrown away by some, but by others it is employed for preparing vinegar and a kind of spirituous liquor.

After undergoing this process, the beans are carried to the *drying house*; this is a wooden shed, sometimes simply a pent house. In the first case the shed is provided with a moveable roof and good ventilation. In this place the beans are spread out upon mats, after being first well rubbed with a little so-called red earth, or with ashes; this operation is performed to remove the slimy stuff that may still adhere to the beans.

Too great a heat must be avoided here, because a too rapid drying would cause the beans to burst, and thence produce mouldiness and decay. During the drying, the beans must be well turned now and then: one workman will suffice for this in a locality 50 or 60 ft. broad. Perfect drying requires 10 à 13 weeks.

Drying under a pent house is being more and more abandoned, because the beans are then apt to be stolen away by human and other pilferers. At present buildings with glass roofs and sufficient ventilation are in use, whereby pilfering is prevented, while the product itself gains in quality; these buildings also give an economy of labour, as the beans can then be left all night spread out, while in the open sheds, they must be put up every evening and spread out again every morning. This collecting and heaping up of the beans at night seems to have an injurious effect on the quality.

Good cocoa can be known by the following characteristics:—The beans must be—also within—of a light reddish brown colour, and brittle, ripe, dry, not musty, but of a somewhat aromatic scent.

After this view of the culture and further preparation of the fruit, we shall now give a description of the chocolate in its various forms and preparations.

B.—CHOCOLATE.

Before using the cocoa the bean must be first roasted, as is the case with coffee. This is generally done in a kind of drums over a gentle fire, when it emits a peculiar aroma.

By this roasting the bean becomes more brittle and at the same time a little lighter of colour; it also loses its acrid astringent qualities and bitter taste.

After this treatment, the bean prepared and worked in several ways is brought into the trade under various appellations.

The first form is that of the peeled beans, which are pressed into small pieces and retailed as *cocoa nibs*; these are, indeed, the purest form under which cocoa can be bought in the retail trade. They must be of a dull greyish red colour; yet they are but too often coloured with Venetian red.

The second form is that of *powdered chocolate*. To prepare this the roasted beans are ground in a mill, consisting mostly in two metal balls working into each other. The thus ground powder contains no additional sugar, only a little meal. It constitutes, therefore, after the cocoa-nibs, the purest form of cocoa.

The third form is the so-called soluble cocoa. This is the form in which cocoa is most used. It consists of the roasted nibs, which after being ground are mixed up with various quantities of starch and sugar.

The starchy substances ought properly to be of sago or arrowroot, but a number of cases occur in which other starches mixed with colouring matter are employed.

The fourth form is that of the so-called *chocolate*. This consists of the beans peeled and ground between heated rollers to a paste, mixed with sugar and various spices—especially vanilla—and then pressed into moulds. After cooling they form the chocolate cakes or tablets.

Besides these there are a couple of other forms, viz. I.—The *coco*, consisting in roasted beans bruised to a warm paste in a mortar, and then ground between two heated rollers and kneaded to a dough with some starch and sugar. II.—The skins of the cocoa-beans mixed with inferior sorts of cocoa, and thus, especially in England and Ireland among the lower classes of people under the name of *miserable*, boiled with water and then drunk.

Concerning the origin of the word chocolate, Van Gorkom says, in the above mentioned work, *De Oost-Indische Cultures*. Vol. II., p. 476, the following:—

"When Cortez conquered Mexico in 1516, he found the cocoa-tree as a characteristic plant of the country; the beans even served as money. Under the name of *chocolatl*, from *choco=cocoa* and *latle=water*, they prepared a rather unsightly beverage, from the roasted, peeled and powdered beans boiled up with a little water, to which sometimes maize meal and spices were added.

The brew thus obtained showed like a foaming mass, of a consistence like honey, which was taken cold. At the expense of Montezama II. 50 cups were prepared daily for himself and 200 for his courtiers. The better classes mixed no maize in their beverage, but used to add honey, vanilla, etc.; at the Court it used to be taken with gold spoons, out of gold vessels.

The Spaniards at the time found warehouses full of cocoa-beans, but even at the present day the Mexicans are as fond of it as ever, and are great consumers, so that considerable imports from abroad are required to supply the deficiency of the home produce."

We generally make our chocolate in the following manner. The necessary quantity is mashed in a kettle with a little hot water poured over it. Then it is well mixed to a smooth paste, and then the kettle is filled up with boiling milk, or else with boiling milk and boiling water. To this is added sugar to taste.

What we call water-chocolate is only an emulsion of soluble cocoa in boiling water. The fluid part of the beverage has, like coffee and tea, an exhilarating effect on the constitution, while the fixed parts, consisting as it does of carbon and azote, constitutes a most nutritious food.

The cocoa-beans contain a fat known by the name of *cocoa-butter*, *cocoa-oil*, *cocoa-fat*, and *Butyrum Cocoa*. This fat is slightly coloured, rather yellowish, and has entirely the taste of the beans. It has the consistence of tallow and the following components:—

Carbon...	76·6	per cent.
Hydrogen	11·9	„
Oxygen	11·5	„
	100·0	per cent.

Its specific gravity is at 15° Celsius 0·91. It is not apt to turn rancid, and therefore it is of great value in medical appliances, where rancidness is to be avoided.

In making milk or water-chocolate this fat often floats at top; this occurs especially when warming up milk-chocolate; its presence slightly indisposes persons of weak stomachs. In good factories this grease is expressed and utilized in another way.

We conclude this part with a quotation from Mr. Van Gorkom's above-mentioned work p. 477:—

"Of course the Cocoa is an important subject in the first account of Cortez to Charles V, and it was sent to Spain as early as 1520 in the form of small cakes, where it met with such ready and extraordinary demand, that, for a long time, its origin was kept secret in order to secure the monopoly of the trade.

"Cocoa, however, like coffee and tea, did not acquire its undisputed popularity without previous warm animadversions from partizans and opponents. Linnaeus, to whom the tree owes its appellation of *Theobroma, i.e., food for gods*, was evidently much delighted with it; whereas Benzoni and Clusius stigmatized chocolate as not much better than food for swine.

"With the more general spread of sugar cocoa came to be more appreciated. Bontekoe's pamphlet: "*het Kruyd Thee, Coffi, Chocolate*" contributed not a little to this. Its use in Central and Northern Europe dates only from 1600, when the Italian Carletti returning from America, brought

over the Chocolate to Florence along with the way to prepare it. About the same time the Court at Paris had received a small quantity from Spain as a costly gift. Even at present the use of chocolate is most general in Spain and Italy, and decreases as we come further northwards.

LOCAL VARIETIES AND PARTICULARS.

In the first part of our article we already mentioned that the cocoa-tree, along with different varieties of that plant, occurs in different places all situate within the torrid clime. The principal of these we will now discuss, following thereby the regions in alphabetic order.

I.—AFRICA.

From the coast of Guinea, and more especially from Monrovia, we get some very good cocoa.

That this sort is far superior to many others appears from the high prices it fetches. It is known by the name of *African cocoa*, and belongs to the species bearing the botanical name of *Theobroma cocoa sativa*.

II.—BOLIVIA.

The cocoa cultivated on the banks of the Mamoré, is as to quality equal to, if not better than, the Maravilla or Caracas cocoa. When the railway net is extended there it is to be expected that this sort will be briskly exported. It bears, like the Brazilian sort, the name of Para-cacao, and is packed in so-called *serrans* or baskets made of skins or hides. Even in Brazil this sort is very much in demand, being acknowledged even there as better than what Brazil itself produces.

III.—BOURBON.

In the Island of Bourbon the cocoa-tree is cultivated betwixt the coffee bushes. The produce however is not great, though of excellent quality, much resembling the Caracas-cocoa from Venezuela.

IV.—BRAZIL.

The plant thrives everywhere here. Many even pretend that Brazil is the home of the cocoa tree. This culture is especially carried on in the districts of Valencia, Camamu and Ilheos, in the Province of Para, as also in the basin of the Amazon, the Madeira and the Salimoes. Very extensive regions are overgrown with cocoa-trees in a wild state, but the culture, and thence the improvement of the fruit, is increasing there from year to year. Yet this fruit of many of the wild growing trees are excellent, especially those growing near the rapids Layes along the banks of the Madeira. The chief supplies come from Para; the culture, however, extends to Bahia, even as far as Rio Janeiro.

The quantity for exportation, however, cannot be much depended upon, especially on account of the frequent inundations which are apt to destroy the crops. The culture is, besides, characterized by great carelessness and slovenliness; no nurseries are provided for young plants, and the only shade the plant receives is from the bananas. The ripe fruit are beaten down from the trees, piled up in heaps on the ground, and are left to ferment there. Three or four days afterwards the fruit are opened and the beans spread out on the ground to dry, in the most favourable case they are spread out on mats instead of on the bare ground.

The twofold crop takes place in the months of December to January and in May to June; the latter crop is the more plentiful. It seems that the climate of Brazil is most favourable for the cocoa tree, for in spite of the great inundations and negligent culture—or rather no culture at all—the tree thrives there splendidly and gives a very profitable yield for 53 à 60 years.

The principal sorts in that country bear the botanical names of *Theobroma Speciosa* and *Theobroma Sylvestris*, while the general commercial appellation is Para-cocoa. The packing for export is in bags.

V.—CAYENNE.

An area of about 650 acres is devoted to the cocoa culture. The Botanical name of the product raised there is *Theobroma Guayanensis;* in trade the fruit is known as *Berbice-cocoa*. The culture is much better here. The fruit are dried in the sun, or else in sheds, through which strong currents of air sweep along the fruit there spread out. On account of its good qualities the fruit is often mixed with drier aromatic Caracas cocoa, especially for preparing chocolate.

VI.—CEYLON.

The culture of cocoa in this island has not extended itself so much as many would desire. Such of the product as has been exported to England has been found to be of a very good sort. In plantations situated in those parts of the island, where the temperature is too high for coffee culture, the plant thrives well, and the extension given to the culture there will render England more independent of transatlantic supplies. Seeds of the best varieties growing in Trinidad have been selected there, and in 1874 more than 40,000 seeds and young plants were distributed by the Botanical Gardens at Peradeniya.

VII.—ECUADOR.

This country yields the greatest quantity of cocoa. The sorts especially growing there are those known in commerce under the names of *Guayaquil* and *Esmeralda;* the botanical name for both the sorts is *Theobroma microcarpa*. The first-mentioned sort is of a mean quality, only half the value of the *caracas;* it is much employed in Germany. The second sort, the *Esmeralda*, is better, but this is little exported, as it is more used for home consumption.

To give an idea of the exports of cocoa from this country we state the following results, the figures of which are given in quintals, Spanish weight; 1 quintal=100 kilograms.

The export amount in 1878 in round numbers:—

To South America	... ...	4,200 quintals
„ Central America	... ...	7,000 „
„ North America	... ...	7,760 „
„ England	... ...	20,704 „
„ Continental Europe	... ...	59,000 „

How unequal the export of cocoa from this country is, will, however, appear from the following table, stating the exports of the given years:—

In 1873	... ...	251,812 quintals
„ 1874	... ...	250,216 „
„ 1875	... ...	176,207 „
„ 1876	... ...	224,739 „
„ 1877	... ...	203,131 „
„ 1878	... ...	98,675 „

In 1877 the price of this sort was 45 shillings per quintal, whereas in 1878 it was 65 shillings.

VIII.—HONDURAS.

Here the sort known as *Soconuzco*, and which during the Spanish supremacy in Mexico, was preserved for the Spanish Court exclusively, grows spontaneously. It gives fruit of 5 à 6 centimetres in length. The very same tree under proper cultivation gives fruit in 5 or 7 years, which then measure 7 à 10 centimetres in diamter and 20 centimetres in length.

IX.—INDIA.

The government of British India does a good deal for the culture of the cocoa-tree in the Peninsula. Great quantities of seedlings of a good quality are obtainable at the Botanical Gardens there. Especially in the neighbourhood of the tract known as the Neilgherry Hills and Terai they thrive well. Also in Coorg people apply themselves to this culture; there the plants are fostered in nurseries, and when they have attained a height of 18 inches, they are transplanted into large holes or pits 15 feet asunder.

X.—MALAYAN ARCHIPELAGO.

The cocoa was imported hither by the Spaniards more than three centuries ago.

In the year 1854 Celebes produced about 100 000 kilograms, and since that time the produce has always gone on increasing. The mean produce of each tree is 5 or 6 lb. a year.

On the London market small quantities of Java cocoa were brought, which was deemed equal to that of Ceylon. In the Philippines cocoa is cultivated only for home consumption. The best cocoa is grown in the small island of Maripipi, but this sort never appears on the market. Then follows in quality the cocoa of Albay, which is considered equal to the Caracas. In Cebu and Negros good cocoa is grown, but in no large quantities, so that they are even supplied from Ternate and Mindanao.

In general the tree thrives as well in the Spice Islands as in Mexico, and is more and more supplanting the less profitable clove trees.

XI.—PERU.

Here the cocoa is cultivated in the gardens of Montana, but in the forests of Peru, the tree thrives also luxuriantly. The sort cultivated here, or rather called from trees growing wild, is the same as the Ecuador, and known there as guayaquil. The export, however, is of very little consequence.

XII.—SURINAM.

In Surinam the cocoa culture has attained great extension of late years. The plantations there were for the most part worked by Creole labourers, but experience has shown these people to be so unmanageable, that they had to be supplanted by coolies. During the last years the crops have suffered greatly from great droughts.

XIII.—VENEZUELA.

The varieties of Venezuela cocoa known under the names of *Caracas* and *Maracaibo*, are acknowledged to be the best of all the sorts produced in the Western Hemisphere, and though the bean was first imported into Spain from Mexico, yet very great quantities were afterwards supplied from Venezuela.

The tree is considered to grow best there in moist, level regions; it then bears one pound of fruit as early as the fifth or sixth year. In the proximity of the coast the tree grows to maturity in the eighth year, but in the Guique districts along the lake of Valencia, and in the Province of Carabobo, it lasts a year longer. Experienced planters, however, aver that the culture covers all expenses as early as the sixth year.

The quality of the Venezuela cocoa has been much spoiled by the introduction of the more profitable, but much inferior sort, called *Trinitario* or *Trinidad*. This is now the main product of the district of Guiria, Maturin, Carupano and the tract along the coast as far as Rio Chico; on some plantations, however, the so-called *Criollo* or *Creole* is exclusively cultivated.

The Trinitario sort is also cultivated in some parts of the Tuy, though the majority of the plantations apply themselves to the cultivation of the *Criollo*. There is thus a supply of good cocoa from this region.

The region that produces the best cocoa extends from the harbour of La Guayra westwards as far as Puerto and Cabelle; especially in the neighbourhood of Ghoroni, O'Cumar, Turiamo, Patanemo and Borburato the product is excellent, while the very best is furnished by the Plantation Chuas, situated near Ghoroni.

From the neighbourhood of San Felipe, the capital of the State of Yaracuy, an average quantity of 5,000 cwt. of very good, though of a mixed sort of cocoa is annually exported.

The district of Chichiriviche, formerly one of the regions that produced the coca, has declined considerably by the importation of the Trinidad sort.

On some plantations where the Trinidad sort is now cultivated, the planters are introducing the red earth of Ghoroni, wherewith they colour the beans.

In general it may be said that Venezuela, especially by the importation of Trinidad seed, has retrograded as regards the cocoa culture; not only has the quality deteriorated, but the quantity exported has also diminished considerably compared with formerly. The best marks are taken by Spain and France; these grow almost exclusively in the coast districts, and are therefore called *cacao de la costa*. The bean is of a dark colour, larger, richer and containing more oil than the other sorts.

The so-called *cacao mezclado* (mixed cocoa) is the product of the plantations on which the indigenous and the Trinidad sorts are cultivated promiscuously. This sort is of a much inferior quality, though the foreign trees have improved by growing in a so much better soil. This product goes chiefly to England and Germany.

The fragrance of the cocoa depends chiefly on the nature of the soil. The very best Venezuela cocoa is furnished by only one plantation, and though seeds of this sort have been tried within the circumference of one mile, yet no where has any sort of equal excellence been able to be reared. This sort is never exported, it fetching there double the price of what Europe is willing to pay for it.

It is beyond all doubt that both the climate and soil of Venezuela are excellently adapted for this branch of culture. The land is low, is now and then inundated, and retains the moisture throughout the summer. The climate is a hot one, so that a moist warmth prevails. The trouble and costs of irrigation are spared without any detriment to the crop.

An important part of the labour of the cocoa culture is applied to the making and keeping in order of trenches to carry off the superabundant rainwater, as nothing is so injurious to the plant as stagnant water. Nine months elapse between the appearance and the maturing of the fruit. The mean produce per tree is 1 or 1½ lb. per season. The age of the trees varies between 20 and 40 years, according to the richness of the soil.

XIV.—WEST INDIA.

In general the culture has not attained a high degree of development in the West Indian Islands. In Dominica even it is conducted in a slovenly way. The trees stand too close, pruning is neglected, shading is unattended to, and fermentation disregarded.

In Guadeloupe the culture used formerly to be as much neglected; at present, however, it is improving, especially in consequence of the introduction of plants direct from Venezuela.

In Jamaica the culture formerly flourished, but the import duties imposed by the English government on cocoa very greatly impeded this industry. Now, however, circumstances have much improved in this respect, and the culture is consequently reviving.

Trinidad still furnishes the most cocoa. More attention is now paid there to the improvement of the seed, and the consequences are patent; at least, a comparison may already be ventured with the Trinidad sort and the Creole sort of Venezuela.

The export amounted in the year 1876 to 8,705,500 lb.; 1877, 8,103,779 lb.; 1878, 2,392,324 lb.; 1879, 11,791,032 lb. Later data are wanting.—*Indian Mercury.*

TRAVELS OF A USEFUL PLANT.

In M. Mangin's work, *Les Jardins*, published at Tours in 1867, a curious account appeared of the importation of the Coffee plant into France, and of its subsequent conveyance to Martinique; and the same story was repeated in the *Famous Parks and Gardens of the World*, an illustrated volume, published in London in 1880, by T. Nelson & Sons. We learn from M. Mangin that the coffee plant first struck root in French soil in one of the hotheuses of the Royal Gardens of Versailles, in 1703. But the gardeners of that time were necessarily inexperienced in the cultivation of exotics, and the plant died from ill-treatment. The Dutch being then large importers of produce from the East, another Coffee plant soon reached the Royal Gardens as a present from the Burgomaster of Amsterdam. The plant flourished, and having been successfully propagated by cuttings, a young plant was given by Antoine de Jussieu to the Chevalier Déclieux, a naval officer, who undertook, at the request of the donor, to convey it to the French colony of Martinique, the climate of which was believed to be suitable, so that coffee might be raised there as an article of commerce. Aided by gods and man, by Minerva, Bacchus, and Hercules, and by various enterprising and colonising nations, from the Greeks and Romans to the modern English, unnumbered plants have been removed from their original stations, to others in very different regions, sometimes in another hemisphere, or at the antipodes, and frequently the new stations have suited the emigrants better than the old ones.

The travels of transported plants have been often attended with danger. Sometimes they have encountered *en route* a latitude too cold for them; sometimes the ship's crew have mutinied, as in the case of the "Bounty" with the Bread Fruit on board; and still more frequently the plants have been neglected. But the French captain was just such an enthusiast as our great plant collectors and importers are glad to meet with, and he brought his pet plant—for he only kept the cutting from Versailles alive by petting it—safely to Martinique. The dangers of the voyage are summed up briefly in the words, "Want of water." Nothing in a sea voyage can be more terrible than a failure of the store of water. The ration of the precious fluid which was served out to M. Déclieux, at last, did not exceed a small glassful daily, and perhaps no other such example

of self-denial in favour of a valuable plant can be offered than that which forms the subject of M. Maugin's very interesting narrative. The Chevalier's devotion to the Coffee plant entrusted to his care saved its life. He suffered severely, but he still persisted in sharing the glass of water with the plant, and he brought it to its destination in safety.

If Professor Asa Gray reads this story I hope he will regard it as making amends for an error I committed a year or two ago in half-killing the wrong plant in these columns. This was done on pretty good authority, too. The Professor discovered my mistake, and corrected it, but he did not give the true version of the story, which I trust has now been done, as it should have been done before if I had met with it sooner.—H. E.—*Gardeners' Chronicle.*

INTERNATIONAL FORESTRY EXHIBITION.

BRITISH GUIANA.—Opposite the Indian exhibits, on the north side of the middle transept, will be found a representative and most interesting collection of woods and other forest produce from British Guiana. It would seem almost incredible were we to enumerate the many valuable trees procurable from these primæval forests. The rivers, being tidal for a considerable distance inland, afford special facilities for the rafting of timber from the inland stations to Georgetown, and various other ports to which ships resort. The principal tree of these forests is the Mora gigantea—until lately well known to our ship-builders, but since the extended use of iron now almost discarded—the wood of which is not unlike Teak, hard and tough. Another valuable timber is the Greenheart, which from its great specific gravity and immunity from the attacks of sea-worms is extensively used in the construction of docks, and for marine purposes generally. Over 100 specimens of trees abounding in the colony are shown, both in a rough and finished state, all of which are well worth inspection by those interested in such matters. Not less interesting than the above is a collection of the parasites and fungi which grow upon these trees. The bush-rope, an extraordinary tree parasite, first makes its appearance at the top of the tree, where the seed had been deposited by birds, and growing downwards frequently strangles the tree in its deadly embrace. The huge and extraordinary fungi here submitted for view—some having the appearance of metal, others of stone or leather—are simply astonishing, and would, to those interested in this way, be a study alone. Specimens of raw fibre and ropes manufactured therefrom are shown as illustrative of fibre-bearing plants in which the colony appears to be exceedingly rich. The material is, to all appearance, of excellent quality, and the threads of fibre of great length. Many notable examples of Indian art industry are also to be seen, such as the buck-pot formed out of a peculiar clay entirely by the hand, in which all their food is cooked; the "shake-shake," or rattle, of the Pei-man, or village wizard, and children's rattles made of Gourds.

ST. VINCENT.—Occupying one of the side tables in the central transept is a series of most interesting and curious exhibits from the Island of St. Vincent. Particularly noteworthy amongst these is a numerous collection of fruit-bearing trees and shrubs, as well as a large representation of their edible products. Of tree seeds there is also a fair collection, and good examples of the various woods used for dyeing purposes. The model of a woodman's hut constructed of Bamboo, and thatched with coarse grass, as used by the natives for temporary shelter, boats, hats, and baskets, are also included in the collection. Chocolate, or rather the fruit of the Cacao from which it is made, and the roots of the plant from which arrowroot is obtained, are well worthy of inspection, as are also the "Old Man's Beard," a native seaweed, and the nest of one of the termite family, popularly called, from its destructive influence on wood, the "Carpenter's Friend," both of which may be regarded more as curiosities than otherwise.

CAPE COLONY.—This name is often applied to the English colony now better known as the Cape of Good Hope. The principal forest of this country is the Knysna which covers an area of about 2,500 miles of the mountainous region between Algoa and Table Bays. Great inducement is now offered for extended planting at the Cape, which, with the measures of conservation recently adopted by the Government will ultimately be productive of beneficial results in not only checking the threatened deforesting of the country, but in clothing the vast flats and waste lands with flourishing woods and plantations. The principal indigenous tree here is the Yellow Wood, which not only attains a large size, but is particularly valuable for flooring purposes as well as the construction of carts, waggons, &c. In the manufacture of furniture the Stinkwood is largely employed, being of an unusually rich appearance and susceptible of a high polish. Black and white Ironwood, Sneeze-wood, which is of great specific gravity; Camphor-wood, the Stone Pine, and the Cape Box, are also exhibits as well as a working model of a forest waggon bearing a variety of the native woods. Of curiosities tastefully arranged on the table, we particularly noted a number of native articles of adornment, such as necklaces and bracelets of Melon seeds, bead-work, hats ingeniously constructed of weeds, and an interesting collection of the now famous Zulu assegais, ostrich eggs, &c.

SIERRA LEONE AND GAMBIA are also well represented by large and varied displays of forest produce. Thirty-two specimens of native trees have been sent by the Government, none, however, of any particular value, but generally well adapted for ordinary purposes. The Rose-wood and Mahogany from Gambia are very inferior, both in graining and texture, to what is generally used in this country, but they may no doubt be turned to good account by the cabinet-maker of ordinary pretensions. Perhaps the most useful of the West African trees is the Koorooloongo, which is not only plentiful but of very superior quality, and used for similar purposes to what the Oak is with us. The produce of the Rubber-Taul, one of the best rubber-producing trees of the colony, is well exemplified in various samples of this commodity shown both in pure and impure states. Other trees are valuable for their medicinal qualities, while for the production of fruits, wine, gums, and various dyes, including indigo, various others are much in request. Samples of the grasses and cereals grown in this country are also shown, as well as ropes and nets made from fibre. One of these fibres is of very substantial quality, as is illustrated by a hammock made from it and forwarded for exhibition. Other exhibits on this stand are the Mandingo saddle, which is made of wood, various cooking utensils, models of native huts, canoes, drinking cups, and chairs; all of which are tastefully designed, and at once convey the idea that the natives are quite at home in these various classes of workmanship.—*Gardeners' Chronicle.*

PINEAPPLE WINE.—I have made wine from grapes for some years, and about two years ago I made a small quantity of wine from pineapples. I will detail the process: The pineapples were peeled, cut into slices, placed in a tub and chopped, or cut with a spade. The juice and pulp were put into a vessel, two-thirds full, a bag placed over it, and left two or three days. Then they were taken out and pressed through a lever or screw press, and the liquid afterward put into a flannel bag. To each gallon of juice two pounds of sugar were added, and the wine put into a vessel of the requisite size, taking care to keep it full all the time, reserving a portion of the wine for this purpose. A bag of sand should be placed over the bung-hole to let the gas escape, and to prevent the ingress of the air as long as the hissing noise of fermentation continues. The barrel should be filled up every third day. After two months paper can be pasted over the bung, and after four months, after clarifying with isinglass and the whites of eggs, it can be bottled. The wine I made proved to be of medium strength, between Burgundy and Port. It retained at the end of eight months the bouquet and taste of the pineapple, and was pronounced by several who drank it the best wine they ever tasted.—*Correspondence Times-Union.*

TEA FIRING.

There is a very good article on this part of tea manufacture in the *Indigo Gazette*, and as we extract it in full we must content ourselves with a very few remarks of our own. It is as follows :—

We now propose saying a few words upon the above subject, which has to some extent altered within the last ten years. If we are not much mistaken, about that time few, if any, firing machines or Dryers had come into general use. We do not say there were absolutely none, but we think the "Sirocco" was about the only one, and it was very primitive compared to what it is now. The amount of fermentation having been decided upon, the fermented mass is carried away and put upon the charcoal fires, or into the Dryer, as the case may be. In the Sirocco there are four superimposed trays, and in the Kinmond there are two, or rather sets of two, and in the Gibbs and Barry Dryer there are no trays at all. The latter is claimed as a greater saviog in wear and tear and repairs. The first and great object to be attained is the stopping of the fermentation as rapidly and as evenly as possible, and to attain this end, if charcoal is being used, the necessity of good sharp clear fires will strike any one as a necessary instrument to attain this end. In the case of the Sirocco the temperature recommended is about 280, and in Gibbs and Barry we believe the pyrometer stands at something like 500. We are not quite, certain if we are right about the Gibbs and Barry. The temperature above an ordinary charcoal fire is about 160 to 180, so it is at once apparent what an extraordinary advantage the planter has who possesses drying machinery. In addition to the temperature being lower than in Dryers, the ordinary choolas are subject to great variations in temperature, especially when the fuel has to be renewed; and if the charcoal, to prevent this, is made red hot before use, the consumption is nearly doubled and it becomes a serious item of expenditure. In our columns, Mr. Allen, the patentee of a Dryer, when writing, called attention to the fact that he had always studied to make his Dryer capable of taking in a full charge of one of Jackson's Rolling tables so as to insure the equal fermentation all over, and a uniformity of color in outturn such as would not otherwise be attainable if all the charge could not have been put over the fire at the same time. There is no doubt something in what Mr. Allen says; but twenty minutes at the outside, even with a Sirocco, would be the utmost difference, and with care in putting the first on just a little underfermented, the result will be found to be pretty satisfactory on the whole. With the Gibbs and Barry the leaf is being fed in continuously, and as the temperature is so high the fermentation is stopped at once, and we must say we think the twist in the leaf must be improved by the continual turning it gets as it descends the cylinder. For the Sirocco the patentee claims that "its pucca batty" improves the tea put through 1d to 2d, per lb. We are not prepared to go so far in this by any means, rather on the other hand; for we believe that the deterioration in the keeping qualities of Indian teas, so much complained of a year or two ago, was to a great extent the result of drying machinery being improperly used in "pucca batty" or final firing. We do not for a moment say that it was due to defects in the machinery, but to an imperfect knowledge of its use by planters. The very high temperature at which these machines are used gives the tea, when passed through, a malty smell and taste which is much liked, and the tea feels dry to the hand; but it is not really cooked through and through, and we quite believe that the re-siroccoing these teas in London would improve their values, because they were imperfectly cured. To pucca battying or final firing teas, the patentee of the Sirocco recommends twenty minutes to fire a tray, but we think that it should not be less than half an hour, and perhaps more. It is impossible for tea to be thoroughly dry in less time, and it is highly necessary that it should be exposed to hot air, even after it is thoroughly dry, so as to fairly, what we may term, set it. Chur planters cannot be too careful in pucca battying, as we consider it is of all the most important. Given that a planter makes first class teas, yet his reputation may be entirely lost by neglecting the final firing. In former years it was customary to put the teas for pucca batty on the fires at sundown, and those teas were taken off at roll-call next morning and packed as quickly as possible afterwards, the final firing taking them about 12 hours, and those were the days when Indian tea had such a reputation for keeping qualities. The complaints have been fowere the last year or two about the keeping qualities of our tnas, and we cannot help putting this down to the planti g community getting better acquainted with the Dryer now in use, and we feel that they will persevere further still until Indian teas again are looked after on account of their keeping qualities.

We may add to the above information that in Jackson's Drier there are ten trays. We agree that the absence of trays is one point in favour of the Gibbs and Barry machine, but as far as our experience goes it is not a very material one for the trays in the Jackson's machine on Abbotsford are only now needing a little repair in the mesh after constant use for 21 months in firing and *pucca battying* some 70,000 lb. of tea. Almost all who have used the Gibbs & Barry drier testify to the improved twist it gives to the leaf; and as to temperature, one planter wrote that he was doing his tea to perfection with the pyrometer at 700°! a difference of 520° above that of a charcoal fire. We fear that the importance of a thorough final firing is not yet realized, or is very often conveniently forgotten, few men having the patience to wait upon their teas for hours. What "*chur* planters" are we do not know, but we trust they were not originally connected with a *ly*. Messrs. Armstrong and Owen both touch only upon "hand-firing." As we are glad to learn from the "Times" that the essay by the former gentleman is "in the hands of everybody" we shall not trouble our readers with any extracts from it, but the following description of the Indian method by Mr. Owen is worth transcribing. He says :—"The air-hole (of the furnace) should be about nine inches high and six inches broad, and no grate whatever should be used. The whole bottom of the stove should be filled with charcoal and kindled until the mass is in a glow; then—and here comes the secret—the fire is masked by a thick layer of ashes, a stock of which is always kept on hand. In using a grate, the charcoal has to be lighted outside and brought to the stove glowing, to prevent the possibility of smoke from illy burnt fuel, and a great loss of heat is entailed be this. One lb. of charcoal does 1 lb. of tea by the Indian method, as against a bushel of charcoal to from 8 to 10 lb. by the latter system. Again 24 and 26 mesh firing sieves have been given up in favour of 12 to 16 meshes. The larger meshes allow the tea to fire quicker, and very commonly the broken pekoe is sieved out through them permanently, thus saving subsequent labour and the use of sieves during firing, at all times a troublesome method. I was al told so, but cannot vouch for the fact, that burning was less common with a large than with a small mesh sieve, scorching being due to the wire getting too hot in the case of the latter."

TEA PICKINGS.

The *Indigo and Tea Planters' Gazette* of July 29th contains some very interesting matter, affording food for thought and light for guidance in affairs theanic. The first leader is upon the proposed formation of a "Darjeeling Planters' Association." This proposal is the outcome of the excitement and displeasure which has been stirring the hearts of our Darjeeling brothers, in consequence of some of their number having raised

the wages on their gardens to the detriment of the interests of the rest. We agree with the editor, when he says:—"It seems to us that the sooner a Planters' Association is formed in Darjeeling for the regulation of all matters appertaining to the guild, the better will it be for the stability and smooth working of the industry in that locality. Granted that there are conflicting interests between gardens, surely these should not be allowed to exist in such prominence as to endanger the general welfare. Individual feeling, personal predilections, and conflicting interests should all be swept away whenever any question affecting the stability of the whole guild comes to the front." And again:—"We can assure the Darjeeling planters that nothing will in the end be gained by isolated action and individual competition for labour, or for anything else affecting the whole community. It is only by united effort and common action, preceded by united deliberation, discussion, and mutual concessions, that the best ends of the industry will be obtained." We need only point to the good work done and doing by our own parent and affiliated Associations to encourage our Himalayan friends to go and do likewise.

The third leader is on "Manure," and is a scathing exposure of the silliness of the remarks made upon this subject by the chairman of the Assam Company. The writer says:—"Such a discussion as took place at this meeting (*i.e.* of the Assam Company), regarding the use of manures and the effect they would have upon that wonderful thing the tea bush, is worthy of the days of tea-planting twenty years ago. It is lamentable, to say the least of it, that such an amount of ignorance can possibly prevail with regard to tea-planting, in what we consider an enlightened age, and reminds one of the times when a Board of Directors of a Company more famed for its debentures than for its dividends, after a protracted discussion, passed and sent out here a resolution to the effect that no more Souchong and Congou bushes should be planted, and that the Manager's attention should be directed to getting a larger proportion of his bushes of the Pekoe kind. Some of our readers may laugh at this as a joke, but it appeared in more than one home print besides being sent out to the Manager in India." That the above is a fact we can very well believe for we do not suppose that even in Ceylon more than twenty in every hundred non-tea-planters know that pekoe is made from the same bush as souchong. After mentioning that he seldom if ever heard that there was not an increase in yield, and in some cases a very considerably heavier yield than would repay cost of manure, &c. the writer proceeds:—"In addition to this the vigour imparted to the bushes gives a superior class of leaf, and consequently a higher average price. Let any one practically acquainted with tea and its manufacture be asked the question why some teas that come on the market are wanting in character, or point, and let that planter visit the garden on which it was made, and he will very soon explain the reason to you and in a very few words, *want of vigour in the bushes*. The question then arises how to replace this which has gone, and the only answer to the question is manure. * * * We do not purpose going into the question of manures more than to assert that the yield of the bushes is much improved by the use of manure, and that almost every planter strives to manure as large an area as possible every year, and does not trust to the bushes in his garden sending its roots further down every year for greater nourishment."

Then follows a Darjeeling planter's essay on 'withering' in which we see nothing worthy of note except the remark:—"Of course we must have *good* leaf to begin with. Succulent shoots containing two, or at most three, developed leaves and the terminal bud—no single leaves, and no woody stalks." We have already said that we do not believe the system of plucking the shoot below the eye, so as to have all *whole* leaves attached to the stalk, to be such a good method of plucking for Ceylon (except in very wet weather), as the *kappo paro*, or two-and-a-half leaf system. Our reasons we have already given.

TEA IN TRAVANCORE.

We have received the following letter, showing the good prospects for the success of tea in South India:—

South Travancore, 30th July 1884.

Dear Sir,—I have read with interest your report of the meeting of the Assam Tea Company. I think we may congratulate ourselves on the fact that the tea-tree has found a congenial home for itself here as well as in Ceylon. I measured a tea-tree yesterday on a neighbouring estate and obtained the following results:—Girth of stem at surface of the ground 30½ inches; girth at two feet from ground 22 inches: height 24 feet. This tree is about 14 years old and has never been cut down or pruned. I should be much obliged by your kindly letting me have a reply in your columns to the following questions:—

1. What height should tea-plants six inches high have attained to in 12 months when planted out in old coffee in moderate soil?

2. When is it considered advisable to remove the coffee?

I have seen on a cacao estate here something very similar to the disease which has appeared in Ceylon. The branches of many trees died back in the month of February and March; some of the trees succumbed altogether, the remainder recovering when rain fell. I attributed this at the time to drought, as the estate in question is situated at an elevation of 400 feet, and this year the dry season set in earlier than usual.—I am, dear sir, yours faithfully, H. J.

The height and girth of stem of the tree measured are certainly satisfactory. We should like also to have had figures showing the girth of the bush itself from branch to branch. In answer to the above queries we should say that in ordinarily good soil a tea-plant 6 inches high when put out should in twelve months reach a height of between 2½ to 4 feet. The answer to query No. 2 depends very much upon the quality of the coffee: if it is at all reproductive it might with advantage to the tea be allowed to remain for the first three years. If it is worthless except for shade, it ought to be removed the second year.

At the trial of Jackson's Manual Roller the other day, some Carolina estate leaf had been sent to Colombo perfectly fresh and sweet, a distance of over 100 miles, but the following paragraph from the *Indian Tea Gazette* shows that leaf can bear a five days' journey, and be workable at the end of it!—

The following interesting account appeared recently in the *News Times*, Vineland, America:—"On Saturday Mr. Hollinsworth, of this place, manufactured what, considering all the circumstances, is an excellent sample of native grown and cured tea. The "leaf" was by arrangement forwarded by express from a plantation near Georgetown, S.C., a distance of several hundred miles, and was nearly five days in transit. The quantity necessarily was small, but demonstrated in a simple manner the perfect practicability of home grown tea being successfully manipulated by experts, solely by means of American machinery and means, the tea being "fired" and dried by an "American" evaporator, which did its work perfectly."

COTTON CULTIVATION IN MADRAS.

In the year ending 30th June 1883, there was a very considerable increase in the cultivation of this staple, the total area under cultivation being 1,708,579 acres, against 1,655,657 in the previous year, or an increase of nearly 53,000 acres. This is the highest figure recorded since the year 1863-4, the time of the American war; and is the more satisfactory as the increase has been gradual since the famine of 1876-7, and has progressed steadily in face of the discouragement caused by the fall in prices at home. The average prices during 1882-3 in the English market were nearly ½d per lb. lower than in 1881-2, which, on a low priced article like cotton, means a depreciation in value of about 10 per cent—a serious item to the cultivators of the staple in this country. The total quantity exported by sea was 598,534 cwt., equal to about 223,400 bales of 300 lb, against 459,351 cwt., or about 171,500 bales of 300 lb., in the preceding year.

The three mills at work within the town of Madras, viz., the Southern India Spinning and Weaving Company, the Madras United Spinning Company, and the Buckingham Mills Company, consumed during the year 57,265 cwt., or say 21,379 bales of 300 lb. This was 2,553 cwt. less than in the preceding year, but showed an increase of 9,134 cwt. over the average of the previous four years. The condition of the weaving classes is said to be satisfactory in Salem, and improving in Kurnool, but in all other districts it is deteriorating. This is not to be wondered at when we consider the annually increasing importation of cheap piece goods from Europe, and the establishment of weaving mills in this country. The future of these classes might be viewed with some concern, were it not that, with the extension of railway construction, other fields of labour will gradually, but surely, be opened up for them.—*Madras Mail.*

FORESTRY EXHIBITION AND LARCH DISEASE.

The following article from the *Scotsman* ought to have, at least, a melancholy interest for Ceylon coffee planters, as showing them how mysterious diseases affecting planting industries on a large scale have baffled all the practical and scientific skill of the West, long before the coffee-leaf fungus was heard of in Ceylon. The Ceylon exhibits at the Edinburgh Exhibition are now in good hands and will shortly be arranged. That the larch planting industry is not destroyed in Scotland we have practical evidence, by recent personal inspections of the fine trees, indeed forests, on the Craighall, Camperdown, Kinnaird and other properties on the borders of Forfar and Perthshires—with scenery equal to any in grandeur and beauty we have seen in the more remote Highlands of Inverness, Ross or Sutherlandshire. Meantime here is the article referred to :—

PRACTICAL FORESTRY EXHIBITS.

Those who may have heard a good deal about the disease which has worked havoc in the larch plantations of the country, and occasioned much loss to the planter of this graceful and valuable conifer, may study its effects in exhibits from the forests of Athole and other parts of the country. The larch, the native home of which is the Tyrol or Carpathians, was tried in Scotland about 150 years ago—the Duke of Athole having the credit of being the first planter of it on a large scale, though in the face of much controversy on the point, and the many "first larches" which exist, it would be unsafe to assign to him the honour which many believe he deserves, of having been the first also to introduce this useful tree into the country. So suitable was it believed to be for covering the moors and bare mountain-sides of Perthshire and other Highland counties, that between 1759 and 1800—a period of forty-one years—it is estimated that over 28,000,000 larch trees were planted, to the advantage of the landowners and the great improvement of the appearance of the country. Of all the trees of the forest, larch is, or was, perhaps the most profitable. It grows fast, attains to maturity within a reasonable period, and its wood when sound is of a very durable character, and can be turned to account in a great variety of ways. Unfortunately the larch in Scotland is not the tree it was. Compared with the older larches, the present generation appears to be a degenerate race. There is scarcely a plantation throughout the length and breadth of the land—a few in Wales are said to have escaped—which has not been attacked by a mysterious disease, in accounting for which practical foresters are by no means agreed. Bad seed, undue forcing in the nursery, deterioration of the climate, exhaustion of the soil, careless management of plantations, fungi, insects, all have been blamed; and as the disease appears to be a many-sided one, it is thought not unlikely that the causes which produce it are complex, and not simple, in their nature. Of all the causes, the arboriculturist will probably incline to the idea that the larch has declined because of the poor seed from which it has been reared—the demand for the tree having sent a flood of worthless foreign seed into the market, which it is impossible to know until its results are seen in the nurseries. Cone gatherers in the larch-woods, being paid at so much per bushel, are not so careful as they should be where they collect the seed—the immature cones from the lower branches being, of course, first taken, while the mature seed on the upper side of branches. In the Exhibition visitors may see examples of larchwood both in an unsound and healthy condition, and even to the uninitiated the contrast they present is very apparent. From the Athole plantations—laid out in the south-western transept—are examples of how the tree in its diseased conditions blisters and bleeds externally, and in that way is deprived of its resinous nourishment, which should go to sustain its wood-making power. Alongside of this exhibit is a young tree in a tub, covered with that pest of the larch plantations, the aphes. The tree looks as if it had been dusted over with a flowery-looking substance, which conceals innumerable microscopical insects, under whose attack many of the young larches receive a severe check, or succumb altogether. Plenty of air, and room for the trees to grow in the plantations are said to be the best means of routing this enemy—close, unthinned, and badly managed plantations being more liable to be attacked with it than others, just as overcrowding in human dwellings generates disease, and tends to degeneration. Sections of larch attacked with what is known in the Highlands as "Rey," but which is nothing more or less than dry rot, are also shown—this occurring apparently in the tree when it has begun to go back through having exhausted the soil in which it stands, or some of the roots having struck into a subsoil which disagrees with it, or other deteriorating cause. These diseased timbers may be compared with one or two splendid specimens of larchwood, also from Athole, with some excellent wood of the same kind from the Stevenstone estate, Devonshire, which was grown in a flat plantation with an open subsoil, or with the fine exhibit of larch from Wollaston, Notts. It is satisfactory to know that the larch disease is rather on the decline; and that the tree is still being very extensively planted. Among the exhibits of pine wood from different quarters may be specially noted here a splendid section of *Picea Nobilis*—an exceedingly handsome member of the great coniferæ family in use for park or landscape purposes—which come from Cultoquhey, Perthshire. The tree, which was planted in 1853, had attained to a height of 55 feet, and was 8 feet 2 inches in circumference. It was blown down in a recent gale; but in the year previous 150 cones were picked off it, a good many of which found their way to the Scottish Arboricultural Society, no doubt to be duly utilized. The visitor can scarcely fail to note the extraordinary size of the yearly ring growths—a proof that the soil of loam and sand in which it grew was greatly to its liking. A root-cut, said to be of one of the first larches introduced into Scotland by Mr. Menzies of Culdares in 1736, and planted at Meggerine, may also be seen by the curious. Practical foresters have been looking with a good deal of curiosity at some Parisian exhibits in the east end of the building, which illustrate the results, in the shape of loose knots and other faults in the wood, of the injudicious pruning of trees—contrasted therewith being the fruits of a more "rational system," which is advocated by the exhibitor, the Count des Cars. The idea of the Count, as explained in print,

is to keep by pruning the tree "in perfect equilibrium" —a system which, it is averred, helps towards the enlargement of the trunk, "the greatest possible surface of leaves being managed in the smallest space." Whatever may be the merits of this French method, there has been a considerable amount of head-shaking over it by British foresters, whose practice seems to be to prune hardwood trees only when young, and even then as little as possible. Foresters may also have their attention called to some models of tree transplanters which are to be found on the central table, among the exhibits in the loan collection. The two-wheeler on the janker principle is a very handy-looking machine, and seems likely to prove serviceable in the forest. It is stated to be capable of removing trees thirty feet high, and weighing two tons—one of its advantages being the ease with which its lever power can be brought to bear in lifting the tree from the earth. There is also a larger four-wheeled machine—more suited, apparently, for park work—by which trees weighing from two to ten tons can be lifted, a weight which indicates a size of tree which foresters would, however, hesitate to transplant. A simple and efficient plan for transplanting shrubs so as to preserve the "ball" intact is likewise shown by the same exhibitor, Mr. James Whitton, gardener, Coltness, Wishaw. In the grounds outside, just behind the refreshment-rooms, Messrs. John Greig & Son, engineers, Fountainbridge, Edinburgh, exhibit a tree and shrub transplanting machine—compact in its construction, and handy in size. The machine in question having been taken down for trial to Trinity Nurseries, lifted the sycamore tree that is shown within its frames clean out of the ground, and brought it to its present position. Closely related to the subject of transplanting are some instructive figures shown on a large chart hanging over the Dean Forest exhibits, which give the result of experiments carried on for the last hundred years in connection with the planting of the oak. These seem to show, in opposition to an old-received theory, that an oak, like every other tree, is better to be transplanted once or twice before being finally deposited on the spot on which it is intended it should grow. In transplanting the tap root is trimmed, and in that way the growth of root fibres encouraged.

An excellent exhibit of forestry subjects well worthy of notice, both from a botanical and practical point of view, is that of Messrs. Vilmorin, Andrieux, & Co., Paris, which is located in the north-western transept. From all parts of the world they have brought together quite a museum collection of dried specimens of plants, cones, and seeds—among the principal objects shown being a most interesting assortment of cones mounted on black stands, all legibly named. Comprised in it are upwards of 150 varieties of pinus, 50 different kinds of abies, and numerous specimens of araucaria, cupressus, juniper, and cedar. —one singular-looking cone being that of the New Holland pine. The collection of seeds includes samples of useful and ornamental trees and shrubs from every region —among others being the teak, mahogany, the eucalyptus, the indiarubber, and the cinchona, with 70 varieties of palms and over 50 varieties of oaks. In glass cases at the back of the stand are dried specimens of the most useful kind of eucalyptus, leaves, flowers, and seeds being shown; and as illustrating their rapid growth, there are displayed some items of the *Eucalyptus globulus* (blue gum), and of the *Acacia dealbata*, grown on Mr. H. Vilmorin's estate in the south of France, which, although only two years old, measure 15 inches in circumference. There are also on the tables a few specimens of various acacia barks, which are now being largely used in place of oak bark for tanning purposes; and as this class of trees is sufficiently developed in ten years, it seems worthy of notice. The same firm also show some beautifully illustrated works on forestry, in English, French and German. It should be said that the space—about 300 square feet—which Messrs. Vilmorin, Andrieux & Co. occupy in the Exhibition building is decorated in an appropriate manner with festoons of cord made from the inner bark of the lime tree, relieved at intervals with cones and pines. Mr. James Barrie, forester to the Honourable Mark Rollo, Stevenstone estate, Devonshire, also sends a well-arranged and representative collection of tree and shrub seeds, and cones and sections of timber grown on this extensive property. There are no fewer than 250 species and varieties of seeds and cones, many of these being from forest trees which do not ripen in our more northern climate. Among the cones were those of the araucaria, the cedar of Lebanon, and nearly all the rarer pines, together with the seeds of the ash, oak, walnut, and sycamore. The sections of timber shown—also 250 in number—are of excellent quality, and bespeak good management as well as a favourable climate and soil. There is also a sample of charcoal obtained from the English willow—a tree whose charred embers is considered most suitable for making gunpowder. The collection is arranged in a methodical manner, so as to show at a glance the distinctive features of each article.

REWEIGHING OF TEA ON DELIVERY.

We understand that an influential section of the importers of tea have agreed to fall in with the wishes of the Loudon Wholesale Tea Dealers' Association in regard to the reweighing of all their tea on delivery to the carriers. It is obvious that under the old system the dealers were placed at a great disadvantage, as frequently there were cases occurring of short weight when a chest of tea reached a country retailer. He made a claim on the dealer in London or on the carrier, and the difficulty of getting a settlement was greatly increased by the want of any record of the actual weight on delivery. It is very satisfactory to us now to learn that in the public sales this week a leading firm of brokers made the announcement that in future their importers and wharfingers had agreed between them to reweigh and keep a record of the delivery weight of every chest as it left their hands. The bare knowledge of this fact will go far to prevent pilferage or loss in transit, and we can only express the hope that such a laudable example may speedily be followed by all the dock companies.—*Home and Colonial Mail.*

THE ORANGE TREE, and the citrus family generally, are proving to be at home in a much wider range of climate and latitude than was at one time expected. Not very long ago it was confidently asserted that oranges could not be grown to profit in the Australian colonies except within a radius of about twenty miles of Sydney. Facts that can be cited show, however, that South Australia, Victoria, New South Wales, and nearly the entire coast range of Queensland from north to south can, under certain conditions, produce this extremely valuable and popular fruit to perfection. It is true that it often proved a failure no matter how carefully planted and tended; and this is the case at the present time in very many localities. The difficulty suggested by this would appear to be in the unfitness of the soil and situation for its permanently healthy and vigorous growth. As matter of fact the orange tree is everywhere a miserable failure when its roots do not get down freely into the subsoil without hindrance from impenetrable rocks or a sour wet clay. Contrary to general notions, the orange must have free course perpendicularly downwards, or it stops growing and quickly dies back. It roots very freely on the surface to start with, but as soon as strong horizontal feeders are established on all sides, a series of roots strike out at right angles from these surface feeders directly downwards, and upon these the longevity and productiveness of the tree ultimately depend. Failures are invariably traceable to impervious rocks immediately under the surface, or to wet and sour clay, neither of which can the orange endure. As a rule it is everywhere thrifty when the deep roots pierce a porous substratum, out of the way of sun heat, and where they permanently escape drought. In all probability it will be moderately successful in shallower soils, with good surface mulching to keep the roots cool, and a supply of water for irrigation purposes during dry weather. The orange is a tree that cannot suffer drought and be healthy, nor can it endure stagnant water within reach of its roots. —*Queenslander.*

CINCHONA IN VICTORIA.—Says the *Australasian* of 5th July:—"Mr. Bosisto, M. L. A., has handed over to the Agricultural department a quantity of the seed of the cinchona or Peruvian-bark tree, which he obtained during his stay in India. The intention is to cultivate the plant in this colony, if possible, Mr. Bosisto believing that in the colder parts of Victoria it can be grown and made remunerative to the cultivator. The first experiments are to be made at the Mount Macedon nursery. It is from the cinchona tree that quinine is made."

NEW INDUSTRY IN MADRAS.—There is a vast field for new industry in Madras. For months past enough has been said about the value of fibre materials. Wild plants called "moorwa" and other kinds grow extensively in Madras. Dr. Forbes has been urging in London their manufacture for commercial purposes, but very little heed is paid. The difficulty of separating the gluish sticky portion from the fibre has now been solved by patents of Ellwood and Smith. Dr. Forbes says these raw fibres can give four crops a year, and a ton of finished produce would leave, after all cost of production and charges on sale, an average profit of 20 per cent. We accept this by no means exaggerated estimate of profit. Now this is just one of those industries which, if developed by capitalists, is likely to enrich Madras as cotton mills have enriched Bombay. May we call upon some enterprizing Bombay mill-owners to embark on this new concern? It will be as profitable as the manufacture of cotton.—*Indian Spectator.*

MAMMOTH TREES.—A correspondent writes to the *Bombay Gazette* :—Your Edinburgh correspondent is quite right in supposing that a "mammoth tree" of 41 feet in circumference need not constitute an Anglo-Indian. The tree in question, of which the rind is in the American section of the Forest Exhibition, is presumably a Californian coniter, probably a sequoia, and no great wonder in its own country. We have in Western India only one indigenous conifer, a tree of no great size, rare and altogether a mere botanist's curosity ; and on looking into Dr. Brandis's valuable *Forest Flora* I find the largest conifer recorded to be a deodar at "Kurasi in the Ravi basin," 44 feet 2 inches in girth at 2 feet from the ground, and 36 feet 4 inches at 6 feet. The following are a few measurements of trees in Western India :—Adamsonia Digitata, the African baobab, called in Maratha Gorakh-chinch and in Hindustani Gorak-imli. One at Junnar, in the Poona district, 47 feet 6 inches, 1871. One at Rijapur (one of the famous "trees of blood") 54 feet, 1877. These measurements were taken at 5 feet from the ground. Tamarind,—one near Sirpur in Khandesh, 45 feet at the same height, 1869. Pimpal tree (*Ficus Religiosa*).—At Akloli, in the Bhiwandi taluka of Tanna, 45 feet at the same height, 1875. This Akloli is not that where the hot springs are, but one march south of it. The tree was the noblest vegetable I ever saw, perfect in form, and as healthy as a sapling. The Adamsonias, like skye-terriers, are beautiful according to their ugliness. There is one misshapen monster of this species in the Satara district, said to be 100 feet in circumference. . . . . Mango or neem trees over 18 feet in circumference are not common ; but I have one recorded measurement of a neem tree in the Ahmedabad district, 22 feet round at 5 feet from the ground.—*Pioneer.* [It would be interesting in this connection to know what is the size of the largest of the baobab trees at Mantota, near Mannar, recently visited by Sir Arthur Gordon. They were first described in British times, we believe, by Major General MacDowall, at the beginning of this century. When "the giant tamarind tree" at Chilaw fell, the late Mr. Casie Chetty wrote an interesting notice of the tree to the *Observer.*—ED.]

THE COST OF A LEAD PENCIL.—"What does it cost to make a lead pencil?" queried a reporter of the New York *Sun.* "First let me tell you how we make a pencil" said the manufacturer. "Do you see this fine black powder? That's graphite. It costs 25 cents a pound [50 cents Ceylon currency.] This white substance is German clay. It comes across the Ocean as ballast in sailing vessels and all it costs us is freight. We mix this clay and this powder together and grind them in a mill, allowing moisture to be added during the process, until the two are thoroughly assimilated and are reduced to a paste about the consistency of putty. This paste we press into these dies, each one of which is the size of a pencil lead, except in length. There are four leads in one of these. After they are pressed we cut them into the proper length, and bake them in an oven kept at very high heat. There we have the lead made. Its hardness is regulated by the greater or less amount of clay we mix with the graphite—the more clay we put in, the harder the lead. The cedar we use comes principally from the swamps of Florida, and is obtained entirely from the fallen trees that lie there. The wood is delivered to us in blocks sawed to pencil lengths, some thick to receive the lead, and others thin, for the piece that is glued over the lead. The blocks are sawed for four pencils each. They are grooved by a saw, the groove being the place where the lead is to be. The leads are kept in hot glue, and are placed in the grooves as the blocks are ready. When that is done, the thin block is glued fast to the thick one. When dry, the blocks are run through a machine that cuts the pencils apart. Then they are run through a machine that shapes and burnishes them, and they are ready to be tied in bunches, boxed, and put out. The different grades in value are made by fine manipulation of the graphite. Here is a pencil that is about the average quality used in every day business. It costs a little more than one quarter of a cent to get it ready for market. We sell to dealers at one hundred per cent profit, and the dealer makes much more than that. Of this grade an operator and the machinery will easily make 2,500 a day." —*Scientific American.*

CROTON* PLANTING.—Soak seed in water for about one hour ; then plant in a nursery (any soil will do) with mouth downwards 2 inches apart. Plant out same as coffee-plants after plants are 4 inch high. Make holes 1 foot deep by 6 or 9 inches wide—deeper will be better. Plant so that top roots be well under surface. I have trees at 20 feet apart which are 25 feet high and join with their branches. As plants grow, cut off lower branches (always reserving eight of upper branches) until you get the tree the height suitable for shade. If for a hedge, fence, or wind-belt, stump the plant at a certain height as may be required, and it will become bushy and strong. Plant : say 6 feet apart and one or two rows to support—the one most exposed to the wind lowest, then higher and higher. The growth being so rapid, if a tree is wanted you must stake well for two years in windy places ; after that, no wind will injure the tree. The plant will bear in second year, and continue to bear the whole year. Little boys should be sent to pick the pods from the ground only once a week. Dry the pods in the sun, crush them by hand or a crusher and sift ; then dry seed again, when it is ready for the market. The tree is always shedding its leaves, and twigs after bearing die back and new twigs with flowers and fruit can always be seen as well as old dead twigs. The roots do not injure other plants. Shade is not dense, and cacao, cardamom and coffee are thriving well under its shade. I think the croton will grow well under Ceará rubber. All trees from which sap is extracted are as a rule growing straight and tall ; if they throw out low branches, these should be cut off as tree should not be allowed to bear seed more than possible. To give good and plenty of sap, therefore, croton as a shrub under Ceará rubber ought to do good to protect stem of rubber trees and give fruit.

* The croton-oil tree is meant, and the directions are by Mr. Holloway.—ED.

PAPER spokes for wheels are among the latest appliances for that ever-increasing article. The paper pulp is forced into iron molds under heavy pressure, where it dries and hardens, and the spokes thus produced are said to be much superior to wood. Paper is fast supplanting wood in many ways.—*American Grocer.*

TEA IN JAPAN.—Tea, says the *Japan Mail*, "stands a fair chance of doing well in the future. Never were the leaves more carefully prepared, a fact due principally to the recent enactment of the Tea Association Regulations. The once universal practice of drying the young leaves by simply exposing them to the sun obtains no longer. Every now and then one hears of confiscations of large quantities of adulterated or carelessly prepared tea, and it is very evident that the local Associations are in dead earnest. The *Ise Shimbun*, however, notices that certain producers in the province of the same name still continue the objectionable practice of mixing pomatum —of all things in the world—with freshly-fired leaves. This is said to give them a bright, seductive colour for the time being, but they are certain to wither, if not to decay, in warm weather. But this and other injurious methods of treating tea is certain to be done away with if the new broom of the local Associations keeps on sweeping as cleanly as heretofore."

THE CHILIAN NUT.—In February last we received for naming some flowering shoots of a very handsome shrub from the garden of J. B. Bohtho, Esq., Greenway Brixham, Devon, which proved to be the Chillian nut, Guevina Avellana, a plant introduced and distributed by Mr. Bull a few years ago, and of which we now give an illustration, with a view to calling attention to it. Mr. Bull well describes it as "an evergreen tree, growing in its native country, Chili, to the height of 30 feet, and furnished with coriaceous imparipinnate leaves, consisting of from two to five pairs of ovatedentate leaflets. The flowers are in simple erect racemes, 2 to 4 inches long, succeeded by globose edible drupes, enclosing almond-like seeds, which are eaten in Chili and Peru. The latter have a mild and somewhat oily taste, while the fleshy pericarp is made a substitute for the Pomegranate." It belongs to the tribe Grevilleæ, of the natural order Proteaceæ, and has proved itself quite hardy in Devonshire, though whether it is so in any of the less favoured parts of the country we are unable to say. Any way, it is a very handsome Shrub.—*Gardeners' Chronicle.*

HINTS ON GARDENING IN INDIA.—We are so frequently asked for a book on Indian gardening, that we gladly direct attention to Mr. G. Marshall Woodrow's little treatise under the above title. It has reached its third edition, which is a sufficient proof that it is appreciated. It makes no pretensions to be a scientific treatise, but gives just the sort of information on practical matters that is wanted by amateurs, treating of soil, manures, watering, propagation, and other garden operations, with notes on the principal garden plants in general cultivation, and monthly Calendars of operations suitable for Western India, Madras, Mysore, and Guzerat. In another edition similar Calendars might profitably be inserted for other districts, such as Sikkim, Simla, Assam, Birma, the Neilgherries, and Southern India. A slight sketch of the metereology of India in relation to the cultural operations based upon it, would also be serviceable. We notice that Mr. Cameron, in the particular portion of the Calendar for Mysore, does give the information required, and we trust that others may in future follow his example. In any case Mr. Woodrow's book is well calculated to fulfil the aim he has in view, and therefore criticism on points of detail is unimportant. —*Gardeners' Chronicle.*

THE REPORT ON THE COCOA PEST.—We understand that this report will shortly be sent in and that its purport will place beyond doubt the fact that the so-called blight is really the effect of *helopeltis antonii*, induced probably by the abnormally dry season, causing a lack of vitality among the trees, which have thus been prevented from throwing off the effects of repeated attacks, as would otherwise have been the case. The flies are reappearing in large numbers on some estates and coolies are employed in catching them, which is most successfully accomplished when the insect is in the larvæ [larva?—ED.] stage and without wings. We shall look forward to the report with interest. In Java, where the insect has done incalculable harm to the cinchonas, they were in some cases kept under by large gangs of women and boys being employed in capturing and killing them, though this was only successful in the case of nurseries or young plantations where the trees had grown to no great height. Van Gorkom in his book on cinchona cultivation in Java, regarding this matter, says that :—

As to capturing the perfect insect, which occurred by millions, that was not to be thought of in the extensive plantations. In small nurseries of ledgeriana cuttings, to whose unimpeded growth most value was attached, it was applied however, and with good results. For 1878 it was stated that the *Helopeltis* had again caused much damage ; it again showed itself in strong force, notwithstanding the severe pruning of the previous year. That the young plantations might, as far as possible, be rescued, it was resolved that the insects should be taken by women and children, a means that is reputed to be the best on the large tea estates. The thousands which were daily captured and killed, of course, could not fellow out their work of destruction, and, where they were thus checked, the plants recovered themselves all the quicker."

It is extraordinary that no ill-effects have been noticed from the attacks of these insects on either cinchona or tea, the former of which they are so partial to in Java, the latter in India.—Local "Times."

MANURE WATER FOR POT PLANTS.—The advantages of manure, applied in a liquid state, whereby nutriment is at once put, as it were within reach of the feeding roots of plants, are well known. But its use is presumably not always carried so far as with advantage it might be. There are few things that are not benefited by it, especially when their roots are confined within the limited space of a pot, where necessarily they have no chance of feeding for themselves in the way open to them when they can spread out as is their nature. One advantage in applying manure in this way, rather than in a solid form intermixed with the soil at the time of potting, is that in the latter way, if enough is given to sustain the plants so long as the roots are to remain in the soil within the pot, more must be used than is well for them to have access to all at once. With such plants as require liberal feeding the double course of mixing some solid manure with the potting soil, and of supplementing this with manure-water, is usually followed with satisfactory results. Another of the advantages of using manure-water to as great an extent as the nature of the kinds of plants to which it is given will bear, is that much smaller pots will suffice than where dependence wholly or in a great measure, is put on solid manure, as the necessary sustenance can in this way be supplied without more extended root room. This is especially the case with soft-wooded plants, particularly such as are grown up quickly for flowering in the autumn or winter from cuttings or seeds put in the preceding winter or spring. In all cases where manure-water is to be given, its application should not be so long deferred as to allow the soil to get too poor to keep up free growth, the want of which is sure to tell in the want of size the plants will show, with a corresponding inability to yield the full quantity of flowers they would were their wants better attended to. Quick growing plants need more food to build up their rapidly developed shoots and leaves, and naturally exhaust the moisture in the soil in proportionately little time, requiring the application of water daily, or all but daily, in dry summer weather, the result of the use of which is that much of the manurial elements in the soil get washed away through the bottom of the pots, leaving the roots with insufficient food unless it is supplied to them in the form of surface-dressing in a concentrated form, or by the application of manure-water, the last of which, when given strong enough, but not too strong, for the plants to bear, and at the right time, is the most certain means of having quick growing things in the best condition, and is equally effective with such as are of a more enduring description.—*Gardeners' Chronicle.*

RETURNS OF RAINFALL IN CEYLON DURING 1883.

The figures prepared in the Surveyor-General's Office appear as a Supplement to a recent *Gazette*, in which the rainfall for 1883 is compared with the means of various periods. The means in a good many places were, no doubt, considerably increased by the abnormally heavy rainfall of 1882, from which there has been a natural reaction to be felt chiefly, apparently, in 1884. In COLOMBO the rainfall of 1883 was excessive, 103·61 inches against an average for 14 years of 87·73. The rainy days were 162 against an average of 154. There was a rainstorm on 8th 9th May showing 5·32 inches, the highest fall in the 14 years having been 11·90 inches on 4th-5th May 1876.

RATNAPURA was also above its average of 14 years, with 168·60 inches against 151·22. The rainy days, however, were only 195 against 217. The highest rainstorm recorded took place 8th-9th May, when 11·42 inches fell.

PUTTALAM showed a rainfall below the average of nearly 14 years, the figures being 41·41 inches against 44·38, the rainy days being only 34 (!) against 69. The explanation of the limited number of rainy days is that the tremendous quantity of 12·06 inches fell in 24 hours, 8th-9th May. This was the severest rainstorm recorded at Puttalam, which is so dry a station that it is the scene of a large manufacture of salt.

ANURADHAPURA also had its highest recorded rainstorm 6·88 inches on 8th-9th May last year, when the rainfall was 69·47 inches against 53·09, the mean of nearly 14 years. The rainy days were 127 against 104 average.

MANNAR is the driest station in Ceylon, but in 1883 it got an enormous excess over its average of nearly 14 years, viz., 57·56 inches against the average of 36·59. There was the greatest rainstorm recorded on 4th-5th February, when 8·48 inches fell in the 24 hours. The rainy days were exactly the average of 60.

JAFFNA, the furthest north station in Ceylon at which the rainfall is recorded, had, like Manoar, an excessive rainfall last year, 67·67 inches against the average for nearly 14 years of 46·44. The rainy days were 82 against 72, and there was a rainstorm of 6·97 inches on 17th-18th November, against the previous highest of 9·55 on 25th-26th November 1875.

TRINCOMALEE on the east coast was also in excess, with 76·35 inches against the average of 62·68. The rainy days, however, were only 96 against 113. A rainstorm of 3·85 inches occurred on 2nd-3rd February, the previous highest being 8·21 on 22nd-23rd January 1878.

BATTICALOA, on the same side of the island, was also above the average of 58·07 with 65·83 inches, the rainy days being 109 against 98. Rain equal to 5·10 inches fell on 26th-27th November, the highest fall in 24 hours previously observed being 10·46 on 6th-7th January 1878.

HAMBANTOTA, in consequence of the result of 1883, a fall of only 28·96 inches (the smallest fall of the year anywhere), takes precedence now of Mannar as the driest station in Ceylon. The average up to 1883 was 36·85 inches. Here there is a large natural formation of salt. The rainy days were 90 against 91, and 2·94 inches fell on 8th-9th May, the previous highest fall in one day being 5·05 on 31st December 1882-1st January 1883.

GALLE showed some excess, 95·06 inches against the average of 90·40 ! the rainy days being 216 against 190; while 5·32 inches of rain fell 15th-16th April, the highest previous fall in 24 hours being 7·66 on 22nd-23rd October 1870.

KANDY, on the other hand, showed a considerable deficiency, 74·02 against 82·24, the rainy days being 171 instead of 193, and the highest rainstorm recorded, 8·95 inches, took place 8th-9th May.

NUWARA ELIYA was slightly below the average of 101·53 inches with 99·62. The while rainy days were 198 against 203; while 6·84 inches fell 12th-13th July against the previous highest figure for 24 hours of 9·11 on 9th-10th September 1874.

BADULLA showed a large excess, 99·61 inches against 75·05, the rainy days being 138 against 85. There was a rainstorm of 4·99 inches on 8th-9th May against the previous highest of 5·72 on 30th-31st Jan. 1882.

VAVUNIYAVILANKULAM got 63·30 inches against an average of 61·99, the rainy days being 98 against 95. The highest rainstorm recorded, 9·26 inches, occurred on 4th-5th February.

RATMALANA ESTATE, GALKISSA, got 97·13 inches against the average of 96·98, the rainy days being 150 against 145. A rainfall of 5·07 took place on 24th-25th Jan. against the highest previous storm of 8·50 on 9th-10th Nov. 1881.

LIBERIA ESTATE, POLGAHAWELA, got less than the average, 93·16 against 97·56, the rainy days being 186 against 178, while the highest rainstorm recorded, 9·30 inches took place 8th-9th May.

HORAKELLE ESTATE, CHILAW, got a considerable excess, 71·66 against 61·98, the rainy days being 134 against 95. Rain equal to 8·50 inches fell on 5th-9th May against the previous greatest storm of 13·99 on 12th-13th July 1878.

RUKAM, BATTICALOA DISTRICT, a tank station, recorded 70·64 against the average of 71·53, the rainy days being 114 against 76. A rainstorm of 5·45 inches occurred on 2nd 3rd Feb., the highest in previous years being 9·50 on 5th-6th July 1878.

GIKIYANAKANDA, PASDUN KORALE, got considerably more than its average of 153·86, viz. 174·79, the rainy days being 239 against 249; while 5·45 inches fell 16th-17th Dec. against 12·00 on 30th-31st May 1878.

LABUGAMA, HANWELLA, recorded 185·73 inches, the highest fall anywhere in the year. The average at this place, whence Colombo is to derive its water-supply from May next year, is 173·64. The rainy days here were 202 against 194. The highest rainstorm recorded, 11·91 inches, occurred on 8th-9th May.

DUNEDIN ESTATE (TEA), AWISAWELLA, has only the figures for 1883 opposite it. They show pretty well: 162·24 inches in 201 days, 9½ inches falling in the great rainstorm of 8th-9th May.

ABERFOYLE ESTATE, RAKWANA, has an average of 129·42 inches for 3 years, the fall for 1883 being 130·26. Here 6·70 inches fell on 8th-9th May.

DOWNSIDE ESTATE, MORAWAK KORALE, has not sent complete returns for 1883, but it is shown that here 11·41 inches fell on 8th-9th May. The previous figures, founded on 1¾ year's observation, were 140·43 inches on 235 days, showing a good tea climate.

MARTIN'S TOWN ESTATE, KUKULU KORALE, got 158·25 inches in 233 days, against averages of 165·79 inches and 232 days. On 8th-9th May, the fall was 7·36 inches.

HAVILLAND, DOLOSBAGE, was 30 inches below its average, with 158·32 inches against 188·00 and 216 days against 225. Of the rainfall of 1883, 10½ inches fell on 8th-9th May.

ST. JOHN DEL REY, BOGAWANTALAWA, DIKOYA, has figures for nearly a dozen years, the accuracy of which can be relied on, and here we have evidence of a first-rate tea climate. The rainfall for 1883, though some-

what below the average of 121·14, was so high as 115·40 on 246 days against 230, six fewer inches but spread over sixteen additional days. Here 9·34 inches fell on 8th-9th May, the heaviest rainstorm observed in 12 years.

FRIEDLAND, in the same district has observations for 3½ years, and the figures for 1883 are 109·43 on 229 days against 110·75 on 234 days. Here the rainstorm of 8th 9th May gave only 6·34 inches against 7 inches on 5th-6th June 1871.

BLAIR ATHOL, DIKOYA, as the result of observations for 5¾ years, shows 141·61 inches in 1883 on 240 days against averages of 145·88 inches on 225 days On 8th-9th May, the rainfall reached 9·65 inches. This place, like the whole region around, is well-suited for tea-culture.

DEESIDE ESTATE, MASKELIYA. With the conclusion of the first half of the year the observations taken here were discontinued, but we know that of 24·85 inches in May, no less than 12 fell on 8th-9th, the highest rainsterm in 9¾ years. The averages established show a fine tea climate, 138·41 inches on 217 days.

MASKELIYA HOSPITAL observations show closely similar results, 129·50 inches on 177 days against 138·81 on 186 days. Here 10½ inches were recorded on 8th-9th May.

GLENCOE ESTATE, MASKELIYA.—Here observations were discontinued at the end of June, but we know that of 23·65 inches in May, 15 fell on 8th-9th. The rainfall for 1882 showed 136·05 on 211 days.

SANDRINGHAM, DIMBULA, did not send complete returns for 1883, but it is shown that 4·65 inches fell on 8th-9th May. This place has an Uva climate, the means of 2½ years being 78·73 inches on 202 days.

BALMORAL ESTATE, in the same district, has far more rain, the means established by 4 5-6ths years' observations being 102·94 inches (say 103) on 232 days. In 1883 the figures were 99·54 on 231 days, 5·80 inches falling on 8th 9th May. Famous as Balmoral has been for coffee, it is evidently equally well suited for tea.

HOLMWOOD, BOPATALAWA, has almost the same climate although the number of rainy days recorded seem somewhat less. The means of nearly three years are 100·94 inches on 199 days with a rainstorm of 7·94 on 28th-29th October 1881. The figures for 1883 were 102·29 inches on 204 days, 5½ inches falling on 8th-9th May.

GINGERANOYA, KOTMALE, has not sent complete returns for 1883, but it is shown that 9·17 inches fell here 8th-9th May. There was a greater storm with 11·40 inches on 9th-10th September 1882. The means established by over 12 years' observations are 149·48 inches on 192 days. Tea ought, therefore, to do well in Kotmale.

FOR RANGBODDE ESTATE, RAMBODA, we have the results of 13 years' observations in the shape of 138·86 inches on 188 days, with a rainstorm of 7·88 inches on 16th-17th July 1878. At the end of June this year, the rain-gauge was removed to Labookelle estate. On 8th-9th May the rainfall here was 3·32.

HETHERSETT ESTATE, KANDAPOLA, is on the other (the eastern) side of the Nuwara Eliya range and at an elevation of 6,500 feet instead of 3,300 at Rangbodde. The means of 5 years' observations here show a good tea climate, 93·50 inches rain on 186 days. The figures for 1883 were 104·37 inches on 197 days, and 4·56 inches fell on 2nd-3rd Feb., the heaviest rainstorm experienced. If the bungalow is really 6,500 feet above sea-level, it must surely dispute with Oliphant bungalow, the eminence of being the leftiest estate bungalow in Ceylon? Is there any estate or private bungalow higher than 6,500 feet? We suppose the resthouse on Horton Plains, at about 7,000 feet elevation, is the highest human abode in Ceylon?

WARWICK ESTATE, NUWARA ELIYA, gives a fair idea of the climate of what used to be called the AMBAWELLA district, now known as New Galway, and classed amongst the Uva districts. It lies near the great mountain mass of Hakgala. The elevation is given at 5,000 feet. We have only the figures for 1883, and they closely correspond with those of Hethersett, the rainfall being 103·47 inches on 164 days, 4·70 inches falling on 12th-13th July.

KURUNDA OYA, MATURATA, had 112·37 inches on 178 days against averages of 112·02 on 176 days, 4·78 inches falling on 12th-13th January.

KABARAGALLA, in the same district, has only the figures for 1883 and these show 107·60 inches on 195 days, 5·34 inches falling, not in January but only July 12th-13th.

KEENAGAHAELLA, BALANGODA, between Haputale and Ratnapura, has means of 5 years, which show a good tea climate, 108·64 inches on 177 days. The figures for 1883 were 119·70 on 179 days, 6·51 inches falling on 8th-9th May.

MORAGALLA, MONARAGALA, is in about the driest portion of Uva, and yet the means of rainfall for 5 years compare well with those for some of the best tea districts in Assam. The figures are, for 1883, 86·78 inches on 169 days against 88·39 and 160 days means. On 8th-9th May 5·21 inches fell, against 5·40 on 30th-31st Jan. 1882.

MADULSIMA HOSPITAL, LUNUGALA, has observations for nearly 4 years, which conclusively establish the suitability of the outlying eastern district of Uva for tea. The figures for 1883 are 111·33 inches on 156 days against averages of 109·86 inches and 145 days. On 2nd-3rd February 5·63 inches fell against 6·95 on 26th-27th October 1881.

MEERIABEDDA, HAPUTALE, has means for 11¾ years, which show 91·09 inches on 158 days. The figures for 1883 (those for July not being received) are 92·45 on 157 days. On 8th-9th May 6 inches fell against 6·92 on 23rd-24th September 1877.

BALLAGOLLAELLA ESTATE, in the same district, but 800 feet higher, viz., 4,500 feet against 3,700, shows for 5 years means of 80·49 inches on 196 days. The figures for 1883 are 87·73 on 178 days. On 8th-9th May 8·68 inches fell.

UDAHENA ESTATE, HAPUTALE.—The observations here were discontinued at the end of June, but it is shown that 8·65 inches fell on 8th-9th May. The means of 5 years are 99·08 inches on 149 days, a good climate for the preparation as well as the growth of tea.

MARIAWATTE, GAMPOLA, the well-known tea estate opened on a portion of what was the first regular coffee estate in Ceylon, shows means for nearly 3½ years of 101·55 inches on 194 days. The figures for 188 were 91·35 inches on 204 days. On 8th-9th May 8·79 inches fell.

NEW FOREST, DELTOTA, gives means for over 7½ years of 105·69 inches on 174 days, the figures for 1883 being 101·71 on 194 days. On 8th-9th May 4·65 inches fell against 5 on 16th-17th May 1877.

RAJAWELLA ESTATE, DIMBULA, once so famous for its coffee, has observations for 14 years, establishing means of 56·69 inches and 117 days. The rainfall in 1883 was short of this low average, the figures being 52·64 inches on 94 days. On 8th-9th May 5 inches fell.

KOBANELLA ESTATE, MEDAMAHANUAWARA, not far off, but more than twice the elevation (3,300 feet against 1,500), gave 143·12 inches on 170 days against means of 159·81 on 172 days. On 8th-9th May 4·53 inches fell.

OODOWERRA ESTATE, BADULLA.—As in the case of so many other estates, observations here have been discontinued; but we know that 3·70 inches of rain fell on 8th 9th May against 4·30 on 30th-31st Jan. 1882. The means of 2½ years are 74·24 inches and 134 days. It has been proved that good tea can be produced on this estate.

GORAKELLE (?*Gowrakelle*) ESTATE, BADULLA, gives means for 7⅞ years of 93·20 inches and 157 days with a rainfall of 4·80 inches on 30th-31st Jan. 1882. The figures for 1883 are 90·46 inches on 170 days, 3·30 inches having fallen on 8th-9th May.

MAUSAGALLA ESTATE, BADULLA, has means for four years of 93·35 inches and 163 days, with a rainstorm of 4·95 inches on 29th-30th Jan. 1882. The figures for 1883 are 102·01 inches on 174 days, 3·10 inches being fallen on 3rd-4th February.

LEANGOLLA ESTATE, MADULKELE, has not supplied compiete returns for 1883, but we see that 5·16 inches fell on 8th-9th May against 7·55 on 5th-6th January. 1878. The means of 7½ years are 115·10 inches on 197 days.

KANDANUWERA ESTATE, ELKADUWA (near Matale), has established means in 11⅞ years of 110·43 inches and 158 days, with a rainstorm of 8·10 inches on 29th 30th Jan. 1882. The figures for 1883 are 109·95 on 181 days, 6·55 inches having fallen on 8th-9th May.

SAMBOOWATTE ESTATE, NAWALAPITIYA, did not supply the figures for the month of May, one of the rainiest, but of 33·36 inches which fell in July, 5·50 fell on 12th-13th The total without, May is 177·15 on 191 days. Probably 200 inches on 200 days will come near the mark, 200 inches being considerably exceeded here in previous years. Tea flourishes with from 70 inches to over 250.

GAMMADUWA ESTATE, RATTOTA, has in 8½ years established means of 116 68 and 123 days. The figures for 1883 were 93·31 on 89 days, with a rainstorm of 7·41 inches on 8th-9th May.

ETTAPOLLE ESTATE, MATALE, gave in 7 years means of 95·10 inches and 160 days, 6·60 inches having fallen on 15th-16th May 1877. The figures for 1883 were 80·03 inches on 197 days, 4·63 inches falling on 8th-9th May.

SAUMAREZ ESTATE, UDUGAMA (in the Southern Province), is the last on the list. The figures are 185·25 inches on 248 days, which shows a first-rate tea climate.

We have thus ranged over climates in Ceylon, where the rainfall in 1883 varied from under 29 inches, as in the case of Hambantota, to nearly 186 in that of Gikiyanakanda. The contrasts are striking enough, but they would be more so, had not such places as Templestowe, Ambagamuwa, disappeared from the list. In many previous years, it showed a rainfall ranging close on 250 inches per annum, with 60 inches, or 5 feet in one month. If observations taken some years age, at Padupolla, a Public Works Department station, could be accepted as trustworthy, we should have maximum figures closely approaching 300 inches as against 30 at Hambantota. The range is certainly from not much over 25 to fully 250 inches, a pretty good range. And in our regions of heavy rainfall saturation of the atmosphere with moisture, cloud and mist have to be taken into account. Ceylon is in the tropics and in the paths of the monsoons (the name given to aggregations of cyclones and their effects), and the deposition of moisture locally is mainly regulated by the features of our mountain system. There are places in Ceylon where raioless days are so rare as to be remarkable, and other places where the rainy days are noted as few and far between. We have, consequently, salubrious zones (where the south-west sea breezes have full play, and on the mountains, all aboye 2,500 feet) and insalubrious, for we have terais and terai fever at the bases of our hills. But on the whole Ceylon is highly favoured with a plentiful rainfall well-distributed, the secret of health in human, animal and vegetable life.

In neither the figures for annual nor monthly fa'ls of ain can we compare with some places on the adjacent ontinent, Cherrapunjee on the Khasia Hills, a spur f the Himalayas facing the tea districts of Cachar nd Sylhet, for instance, those districts not getting the rainfall but feeling the effects in floods which are occasionally destructive. Once in about ten years we have exceptional floods in Ceylon, which severely try all structures against which their waters are projected, especially irrigation works. But what would our readers say to nearly 41 inches of rain in one day and 131 inches in one month? In June 1876, from 12th to 16th, 114·14 inches fell in five days: 22·84 on one day, 30 45 on another, and 40·80 on a third. Between 1865 and 1880, the annual average established was close on 500, the exact figures being 493·19 thus:—

	Inches.
January	0·76
February	2·76
March	8·79
April	30·90
May	51·43
June	115·88
July	130·84
August	79·62
September	56·10
October	13·65
November	2·23
December	0·23
Average annual rainfall	493·19

If the rainfall registers of 1860 and 1861, abnormally heavy rainfall years all over Bengal, could be trusted, the figures for those two years would be 699·73 and 905·12 inches. But a maximum of 600 inches, or 50 feet, is probably nearer the mark. Mr. John Eliot, M. A., Meteorological Reporter to the Government of Bengal, thus notices the physical circumstances which produce such a vast precipitation of moisture:—

Cherrapunji is a small Indian station situated in the south-west of Assam, on a small plateau forming the summit of one of the spurs of Khasia hills. These hills, which rise on the south with exceeding abruptness, have the Bengal plains and low lands at their base. Cherrapunji stands on the summit of one of these hills at an elevation of about 4,100 feet. The hill on which it is situated rises precipitously from the low lands of Cachar and Sylhet, which are barely 100 feet above mean sea level.

During ths south-west monsoon the lower atmospheric current advancing across the coast of Bengal has a direction varying between S.S.W. and S.E. in Lower and Central Bengal. It thus advances almost directly towards the hills of Western Assam.

The mountain ranges cause a very considerable deflection of the current. One portion of air is forced upwards as an ascending current with a velocity directly dependent upon the strength of the current in the rear, and upon other conditions which need not be enumerated.

The rapid diminution of temperature which accompanies expansion due to ascensional movement of air, is usually followed by rapid condensation in the case of a moist current, such as the south-west monsoon current.

The rainfall at Cherrapuuji is not due to any abnormal local conditions of atmospheric pressure, air movement, &c., but simply and solely owing to the presence of a vast mechanicial obstruction which converts horizontal air motion into vertical air motion.

This fall is very local; at Silhet, not thirty miles further south, it is under 100 inches; at Gauhati, north of the Khasia in Assam, it is under 80 inches; and even on the hills, twenty miles inland from Churra itself, the fall is reduced to 200 inches.

Cherrapunji is surrounded, or nearly so, by vertically ascending currents of saturated air; the dynamic cooling of which is the cause of the enormous precipitation which has made this place famous.

Our readers will notice that the rainfall of the Indian tea district of Sylhet is under 100 inches, while in Assam it is under 80. But 80 inches in Assam means a heavy rainfall for four or five months, with dry and even wintry weather for a considerable portion of the year. In Ceylon, where the rainfall ranges from 70 to 200 inches, drought is rare, while frost and hail are practically unknown. At any rate, we suppose a

few hundreds of pounds would cover all the damage ever done by frost and hail in Ceylon. In India the tea-planters have a very different tale to tell.

THE ANNUAL REPORT OF THE JAMAICA PUBLIC GARDENS AND PLANTATIONS

or the year ending 30th September, 1883, by D. Morris, M.A., F.G.S., Director, reached us some time ago, but the necessity of dealing with the important political intelligence which has reached us from the east and west of the world has prevented earlier attention to this interesting document.

The report speaks of activity and progress in the introduction, propagation and distribution of plants of economic value. Jamaica seems to have entered on a dry cycle, the rainfall of the past three years having been only half of that of the three previous years. The failure of the May rains had affected crops, the export of sugar having fallen below that of 1882.

Mr. Morris states:—

As mentioned in the annual report of the Collector-General for 1833, "there was an increase in the export of coffee as compared with 1881-82, although a falling-off of 1,101 cwt on the average of the preceding four years. The export of this article for 1883 was 84,358 cwt. of the value of £160,617. In pimento there was an increased quantity exported but with a great retrogression as regards value owing to the low prices then ruling. The total exports of pimento were 85,282 cwt. of the value of £102,678. The trade in fruit is still sustained with great activity and it is satisfactory to observe that the export of bananas continues to increase. The output of oranges, although not so good in point of number as in the preceding year, yet the fruit is invoiced at better prices, owing, I believe, to greater demand caused by a partial failure of the Florida crop. Pine-apples, although exported in somewhat diminished quantity, have so increased on the average of the preceding four years as to warrant the assumption that they will hearafter form no insignificant factor in the aggregate value of fruit exports."

The *aphis* had done some damage to sugarcane, but Mr. Morris believed that

With care and judgment on the part of planters the recurrence of this pest need not be feared in an aggravated form and especially in districts where good drainage and the judicious use of lime enter, as they always should, into the regular cultural operations of all sugar estates in moist parishes.

He adds, with reference to the disappearnce of mole-cricket which had damaged pastures:—

This spasmodic or intermittent character in the attacks of insect pests is in accordance with their general habits in all parts of the world; but it is well for us to note their appearance and disppearance with great care in order that we may, thereby, be prepared for their attacks and reduce the amount of damage they do to our crops to a minimum.

We quote as follows:—

A paragraph in my last report as regards the indiscriminate destruction of small birds in this island has, I am glad to say, attracted attention, and it has been the means of sugge ting measures whereby it might be checked if not entirely stopped.

The mungoose, an importation from India, to destroy rats on sugar estates continues to multiply and spread, not only on sugar estates, but on the highest mountains, as well as, along shore even amidst swamps and lagoons. The sugar planters have unquestionably greatly benefitted by its introduction and rat-eaten canes are now hardly known where, formerly, in spite of an expenditure in some cases of two hundred pounds per annum to destroy rats by poison and dogs, large quantities of rat-eaten canes were ground for the still-house, being unfit for anything but being made into rum.

The negro settlers and persons not connected with sugar estates complain of the ravages of the mungoose amongst their poultry, and, even, accuse it of destroying fruit and vegetables. The fact remains, however, that poultry is still fairly plentiful in the country districts; and the mungoose is, often, only mentioned as an excuse for raising the price. Having had mungoose in confinement I tested the fact that they will not eat either, banana, sugar cane, or ordinary field vegetables except when driven by extreme hunger such as they are never likely to experience in a state of nature.*

The mungoose being really a cat is not likely to depart from the inherent instincts of its kind; and while there are rats, mice, lizards and other small vermin for it to feed upon it will not attack anything of a vegetable character. The mungoose is however disturbing, greatly, the distribution of animal life in the island; and the harmless yellow and other snakes, lizards, ground-hatching birds, the interesting cony, and many members of our indigenous fauna are likely to become extinct at no distant period.

Mr. Morris then refers to his visits to Honduras, St. Helena, Madeira, England and the Amsterdam Exhibition.

In dealing with the Castleston gardens the Director states:—

To the plantation of Trinidad varieties of cacao, formerly established with a view to test and prove the best kinds, as well as to enable the Department to meet the steadily increasing annual demand for pods, have, this year, been added 160 plants of the commercially famous Caracas variety. They are planted at the southern end of the experimental garden. Some of the plants, I regret to say, have failed, owing to their age and large size when put out from pots as also for the want of established banana shade, at the time they were planted; but the survivors are healthy and will in time, I doubt not, form a profitable plantation.

The demand by planters, in the year under review, was for cacao pods rather than plants; and it is regretable that their wants, owing to the small number of bearing trees, were so insufficiently met.

The 150 pods were all that could be spared of the crop borne by the trees which survived the hurricane of 1880. But I am pleased to be able to add that independently of these, large quantities of good pods (with which to establish nurseries and plantations) were regularly sold by some of the settlers in the Wag Water Valley to various planters of the central and western parishes: which sales were to some extent the results of personal interest and exertions of the Superintendent on behalf of both producer and buyer.

It may be of interest to botanists, at least, to learn that by artificial fertilization a cross has been effected between Hibiscus sinensis and the new and very distinct-looking H. schizopetalus, from Eastern Africa. H. sinensis was the seed-bearing parent. The leaves and flowers of the resultant seedlings are seemingly intermediate between those of the parents: the respective vegetative and floral characters of the latter may be said to be evenly blended in the seedling issue.

In addition to the above many new and fine varieties of Hibiscus sinensis and also of Coleus have been raised and are now being distributed from the garden.

The cinchona plantations are 4,500 to 6,500 above sea level and at 4,850 feet, the mean temperature is 63°, with an average rainfall for 11 years of 115·58 inches. From the report of those gardens we quote a few paragraphs of special interest:—

Several thousand plants of Cupressus macrocarpa, C. Lawsoniana, Pinus insignis, P. sinensis, P. Tuberculata, and Juniperus Bermudiana have been raised for distribution and for the purpose of planting shelter belts in the most exposed Cinchona fields.

The seeds from which the plants of the native Juniper (Juniperus Bermudiana) were raised, were procured by exchange of Cinchona seeds and seedlings with planters in the neighbourhood. This seed is found to germinate quickly if slightly fermented, then deprived of its pericarp by rubbing through a fine sieve, and sown near the surface in nur-

* On one occasion, a rat placed alive in a cage with a pair of mungoose was struck by the male, but, the latter not being hungry, the attack was not followed up. This rat afterwards lived in the cage with the mungoose for several days; but this isolated instance does not disprove the fact that the mungoose does kill rats, for other rats placed in cages with mungoose were instantly killed.

sery beds in the open air. The trees is particularly hardy, grows in the poorest soil and forms an excellent shelter belt against strong winds.

Cardamom seeds were received from Ceylon and there are now in the nurseries several thousands of these plants ready for distribution. The length of time (four months) these seeds take to germinate at this elevation is a noticeable feature. Cardamoms evidently do better at a lower elevation and it would be well to cultivate them in moist hollows at elevations below 3,000 feet. In connection with the nurseries it might be mentioned that having some Cinchona officinalis seed which had been in hand some time and therefore not considered fit for distribution, it was determined to try the experiment of broadcast sowing at 5,500 feet. Accordingly a spot was selected in a field of three-year-old C. officinalis. The ground was covered with decayed fallen timber, upturned roots, and in some places the soil was partially composed of peat, and generally contained a large amount of humus. Seed was freely distributed by hand on this ground, and particularly under and near the fallen trees and roots, and also along the margin of the forest, with the result that we have now many thousand seedlings 3 to 8 inches high, the trees of C. officinalis 4 feet to 8 feet high and about 3 years old forming the only shade. The seed was sown in October and November, being the most humid season. Self-shed seed from the young trees have not germinated in equal proportion, consequent, probably, on its ripening during the drier months.

Lower Buzza Plantation is thus reported on:—This plantation contains only trees of C. succirubra from which it was intended to harvest a full crop of bark; it was, however, determined, with the consent of Government, not to do so, but to harvest a crop by the shaving process instead. This was done in order to determine whether, in this country, a more profitable return might be yielded by this process.

The total number of trees barked was 2,144, yielding 5,218 lb. wet bark—giving an average of 2·43 lb. per tree.

The average weight of bark brought in each day per man was 50¼ lb. which, calculating labour by skilled hands at 1s 6d. per day, gives the cost of wet bark per lb. at ·36 pence for harvesting.

As to the effect of the process on the trees it is found that at the end of twelve months not a single tree appears to have suffered. Moreover, the renewal of the bark has taken place all over the plantation in almost a uniform manner, and another crop might at once be harvested equal if not superior to the last.

It is to be remarked that had not the experimental shaving process been decided upon, a much larger quantity would have been harvested. As it is, the original trees are still standing with bark much increased in value by the process. It is now definitely ascertained that renewed bark produces a larger percentage of alkaloids than the original. Experience in Java with Ledgerianas, however, seems to prove that good time must be given to the renewed bark to form.

What Mr. Morris called "Ceylon willows" in a previous report he now describes as *Ficus Benjamina*, stating:—

The plants of Ficus Benjamina which were planted on the opposite side of the avenue in 1882, have grown remarkably well; this is evidently a tree well adapted for growing in the plains; it has a graceful drooping habit and makes an excellent shade-tree. The palms (Oreodoxia regia) which are planted alternatel with the Ficus have so far not done so well; they are however, in a healthy state and are growing, but slowly.

We hope soon to see the exquisitely graceful *Ficus* referred to adorning the sides of streets and roads in Colombo and our other towns. The specimen we brought from Java has flourished at Mr. Wm. Ferguson's residence, and cuttings from it will speedily be available.

The part of the report referring to the cultivation and distribution of economic plants we quote as follows:—

Cacao:—The cultivation of this article in connection with bananas is making good progress and I estimate that nearly 1,000 acres are now established with cacao.

Increased attention appears to be devoted to the curing of the crop and under the influence of interest lately taken both by Government and the Institute of Jamaica the quality of Jamaica cacao in the London market is increasing. On samples of Jamaica cacao lately submitted to London brokers the following reports have been received. Extract of a letter from Messrs. J. S. Fry & Son, of Bristol:—"Your sample is good. The cacao hitherto imported from Jamaica has not fetched a high price in the market. It seems somewhat imperfectly cured, many of the beans are defective and mouldy, and the cacao looks as though it had been picked unripe. In the best samples the kernel or nib is of a nice pale colour. The consumption of cacao in England is increasing steadily though not very rapidly."

Mr. Thomas Christy reports as follows:—"I am in receipt of your favor of 17th January together with a bag of cacao, and I at once proceeded to exhibit it on our market. It was very much appreciated and one of the questions asked was, if it was 'picked,' that is to say, if all the small berries had been thrown out, as it was such a very fine sample and it was valued as high as from 80/ to 90/ per cwt. by some of the buyers.

"In some of the numbers of the 'New Commercial Plants' I have called attention to the colour of the Ceylon cacao, the earth imparting to it a peculiar red tinge which is much valued. The sample of Jamaica cacao is not very deep in colour. One of the best arguments I had to meet the question of 'picked sample' was that upon opening some of the beans we found a small proportion had not been cured, the fruit not being entirely ripe.

"Messrs. Lewis and Peat, who have a very large connection and who I always find most willing to assist me in introducing new products and produce from new places, took a portion of your sample and showed it amongst their friends, and a copy of their letter and report will save me repeating some of the remarks that I heard from friends to whom I showed your cacao:—

"'*Jamaica Cacao*:—We have carefully examined the sample you hand us and find it one of the very best prepared specimens of Jamaica-grown cacao we have seen. It is prepared like Trinidad, and would find a ready sale here both for home trade and export. It is rather wanting in strength and flavour and we should imagine this could be remedied either by being grown on higher ground or improved soil. Its value here today we estimate at about 75/ per cwt.' Suffice it to say that you could not have a better criterion of the success of your experiment than to be able to publish the market price that is accorded to your cacao.

"Before I named where the cacao came from it was classified as 'high class Trinidad.'"

In a letter received from Messrs. Park, Macfadyen & Co., Lime Street, London, they report as under:—

"We have the pleasure to own receipt of your esteemed favour of 17th January as well as the sample of cacao therein referred to and, as requested, have had the same thoroughly tested and now beg to report thereon, as follows:—*Quality good, red dullish, highly dried, dullish break, little flavour*, value about 72/ at 74/ per cwt. The curing of this sample is a great improvement upon what we are usually in the habit of receiving from Jamaica and would, we think, work itself into favour. The price of ordinary Jamaica just now is 66/ to 68/ per cwt. Placing your sample alongside Trinidad production it would require a practiced eye to tell the difference, and if the flavour could be more fully retained a higher value would without doubt be attainable. We will at all times be pleased to prove of service to you on this side."

Maragogipe Coffee:—A few beans of this coffee were received from Messrs. Thomas Christy & Co., from which about a dozen seedlings have been raised. It appears to be a new variety of the common coffee found in Brazil, which has a much larger leaf than the ordinary coffee tree. Mr. Christy mentioned "that it grows with extraordinary vigour, and trees three or four years old were already eight or ten feet high and full of fruit. The tree seems to come into full bearing much sooner than the ordinary coffee, and the bean is very much larger. Altogether the weight of coffee per acre must be very much more when land is planted with Maragogipe than with the ordinary coffee tree."

Liberian Coffee:—Trees of this coffee at Castleton are in good bearing and seeds in quantity have been distributed to plantations in different parts of the island. A fine sam-

ple of this coffee was lately exhibited by Mr. James Harrison, from Winchester Estate, which was of excellent colour and uniform size.

Cardamoms:—Plants of this valuable spice are growing well at Castleton and at Hope. A few seeds have been produced by plants at the latter establishment. I have had very encouraging reports from planters who have tried Cardamoms at elevations under 2,500 feet, which would appear to be the best localities for Cardamoms in Jamaica.

It may be mentioned that boxes of Cardamoms containing 100 plants established in soil can be forwarded free to any outport on receipt of a remittance of ten shillings.

Nutmegs:—I have to report moderate progress in the cultivation of nutmegs, but not nearly in proportion to the suitability of many districts in Portland and other parishes for the cultivation of this useful spice. Well established plants in pots are always kept for distribution.

Tea:—The experimental plantation for tea at 5,200 feet has lately been pruned and seeds should be produced towards the close of 1884 in large quantities. Tea seed, it may be mentioned, will not bear long transit unless packed in earth. Tea plants are available in limited numbers ready for planting out.

Cinnamon:—The forms of Ceylon cinnamon propagated by layers and plants continue to be distributed in small quantities.

Kola Nut:—As the interest in this plant has so greatly increased it is found that it is much more widely distributed in the island than was at first supposed. During the proper season seed nuts may be obtained in large quantities, as also a few plants in pots suitable for distribution.

Vanilla and Black Pepper:—Numerous cuttings of these with full directions as to treatment, have been distributed by post and the cultivation is slowly extending.

Mangoes:—The export of mangoes is not extending although the fruit is so abundant and so largely sought for in America. This is chiefly owing to a want of care in picking and carefully selecting the fruit as well as in packing. It may be mentioned that the new East Indian varieties possess much better keeping properties than the ordinary No. 11 of Jamaica, and grafted plants of the former are always available at the Hope Plantation. The export of mangoes for the year 1883 was 81,320 of the value of £106.

Pineapples:—For export purposes the more common kinds such as the Jamaica black pine appear to be in greater request than the choice Ripley as the latter does not travel so well. During the past year the Cuban and Scarlet pines from the Bahamas, as well as the cultivated Pitch Lake pine of Trinidad, have been introduced for experimental purposes. A fine selection of the best English pines from Windsor Castle and Lord Carrington's nurseries, have also been obtained through the Royal Gardens, Kew, which are doing well at the Hope Plantation. The export of pineapples last year was 7,722 dozens of the value of £1,158.

Oranges:—The export of oranges chiefly to the American market has now reached the large number of 34 millions of the estimated value of £37,560.

With a few notable exceptions, however, the cultivation has not much improved and the self-sown trees which yield this large return are practically wild. The Tangerine orange is receiving greater attention, and I am hopeful that orange culture in Jamaica will before long be taken up as seriously and as intelligently as it is in Florida and California. Orange trees on lands in the neighbourhood of the Rio Cobre Irrigation Works are doing well; and there is no reason to doubt that orange-growing as a regular industry—which it is not now—would prove highly remunerative.

Ginger:—The cultivation of ginger in Jamaica would appear to be gradually dying out. This is no doubt owing to the smaller yield of plants cultivated so persistently on the same land, to the uncertain nature of the crop no less than the difficulty experienced in many districts in curing it properly. Only the richest and best lands are suitable for the ginger plant and as it is very exhausting crop its continuance as an industry in the island is entirely dependent on the reserve of good land still available in the districts in which it is cultivated.

The export of ginger during the last five years has averaged 7,036 cwt. of the value of £16,000 compared with 11,219 cwt of the value of £22,000 during the five preceding years 1874-79. This shows a falling off at the rate of 36 per cent.

Bananas:—This is the most extensive and most valuable fruit interest in the island. The export for 1883 were 937,951 bunches of the value of £93,795, which is more than six times the number and value of those for 1877.

As the bananas are utilized in many cases as nurse-plants for cacao, nutmegs, oranges, Liberian coffee, cinnamon, coconuts, cardamoms, and rubber-yielding plants the banana culture is leading to numerous permanent cultivations which will remain after the bananas have died out. In this respect it is the means of permanently reclaiming extensive areas which hitherto had been utterly neglected.

Para or Brazil Nut:—Several thousand seeds of this plant were distributed over the island in May, 1881, and although many failed to germinate, it appears that where carefully watered and treated for several months—some even for two years—they have done well. In the nurseries at Castleton and the Hope a few plants are still available for distribution.

Sapucaja Nut (Lecythis sapucajo):—About thirty plants of this were successfully raised at the Hope many of which are doing well in suitable localities.

Tonquin Bean:—This is a fragrant seed yielded by Dipterix odorata, a tree of South America, now naturalized at the Castleton Gardens. The odour resembles that of new mown hay, due, it is said, to the presence of Coumarine. An allied plant under the name of Sarapia or Venezuelan Tonga bean has lately been received from Trinidad.

Coca:—This plant known to botanists as Erythroxylon coca is well established at all the establishments and if a demand arose for its leaves (which are said to contain a slightly stimulating and tonic principle) it might be cultivated to a considerable extent.

Sarsaparilla:—The cultivation of this plant is confined to a small district in the Parish of St. Elizabeth where settlers treat it as they do the ordinary yam. The plants, mostly seedlings, are put out at about 20 feet apart and trained to stakes and trellises. They begin to yield crop, consisting of the roots (washed and dried in the sun) in about two or two-and-a-half years. Mr. Syme, who visited the district, mentions that as much as 20 pounds of dried roots are yielded per plant as a first crop and from 30 to 40 pounds as a second crop. At the present price of sarsaparilla, the gross return is estimated at 30s per plant or at the rate of £50 per acre.

Annatto:—The seeds of this dye plant (Bixa orellana) are still exported in fairly large quantities in spite of the low prices at which they are quoted in the New York market. The exports last year were 131,288 pounds of the value of £1,367.

Fibre-yielding Plants:—Increased attention is being devoted to the utilization of the many native plants capable of yielding fibre. The most promising plants appear to be the various species of Agave, Furcræa, Sansevieria, and the China grass, Boehmeria nivea. Furcræa Cubensis is widely distributed in the island and especially in the parish of Westmoreland where it is known as "Silk grass." The common Keratto yields a good soap as well as a fair fibre. The bamboo is utilized also for fibre purposes, being exported in a crushed state and packed by hydraulic pressure in convenient bales. The New Zealand flax has been introduced and is now established at the Cinchona Plantation.

Rubber-yielding Plants:—The Ceara rubber, Manihot glaziovi, and the Central American rubber, Castilloa elastica, appear to be best suited to the climate and soil of Jamaica. With regard to the latter I have described it as follows in a recent work entitled the "Colony of British Honduras," see pp. 74, 75, 76, & 77:—"Next to cacao the most interesting plant found wild in the forest of British Honduras is the india-rubber tree, called by the natives 'Toonu.' This tree (Castilloa elastica), a member of the breadfruit family, and whose product is known in commerce as Castilloa, or Central American rubber should become, in course of time, one of the most important cultivated trees in the colony.

"The large and increasing demand which arises for india-rubber for all kinds of appliances in arts and manufactures renders the production of this article an industry of great value. The original supplies of india-rubber, derived from various trees growing wild in tropical forests all over the world, are likely at no distant date, to fall far short of

the demand; and hence these supplies will require to be supplemented, if not, indeed, to be replaced, as in the case of cinchona barks, by the produce of trees under cultivation.

"The Toonn in British Honduras is found in most of the Cohune ridges of the country, and especially along the banks and in the valleys bordering Mullin's River, Sittee River, and the Rio Grande, in the south; as well as along the Sibun River and the upper waters of the Belize River in the west.

"The tree is very abundant in some places, although daily becoming scarcer in the immediate neighbourhood of settlements. It grows to a height of about 40 to 50 ft. has a thick clean stem, about 2 ft. in diameter at the base, and in habit of growth much resembles a breadfruit tree, to which, indeed, as mentioned above, it is closely allied. The leaves are large, oblong in shape and clothed, especially in the young state, with a dense coat of hairs. The flowers appear in February or March: they are monœcious—that is, have the male and female in different flowers in the same tree. The fruit of a brownish-green colour when ripe, has very much the appearance of a raspberry flattened or depressed, about an inch in diameter; the numerous seeds being massed together and enclosed in papery capsules, covered with a brown tomentum. When taken out of the husk the seeds are of a whitish colour, about as large as castor oil seeds, and evidently soon lose their vitality. The best way to collect the seeds, which ripen in May or June, would be to gather fruits just before they burst, and to spread them out for a few days under shade.

"When intended to be shipped, the seed should be packed in earth and carefully fastened down. To establish plantations the seeds might, in the first instance, be planted in open nurseries, or in boxes or beds, raised some 4 or 5 feet above the ground, so as to be beyond the reach of ants and mice. The plants thus raised might be transplanted at the end of twelve months, and put out in their permanent places in the field. Where, however, seed is abundant and ants and mice are not likely to destroy them, two or three seeds might be planted out at once, 'at stake,' as it is called, in the same manner as recommended for cacao. In the latter case, if all three grow, one strong plant might be left and the other two either transplanted to supply vacancies or destroyed.

"The Castilloa rubber-tree is fit to be tapped for caoutchouc, or the elastic gummy substance produced by its milk, when about seven to ten years old. The milk is obtained at present from trees growing wild, by men called rubber-gatherers, who are well acquainted with all the localities inhabited by the Toonn.

"The proper season for tapping the trees is after the autumn rains, which occur some months after the trees have ripened their fruit, and before they put forth buds for the next season. The flow of milk is most copious during the months of October, November, December and January. The rubber-gatherers commence operations on an untapped tree by reaching with a ladder, or by means of lianes, or tie-ties, the upper portions of its trunk, and scoring the bark the whole length with deep cuts, which extend all round. The cuts are sometimes made so as to form a series of spirals all round the tree, at other times they are shaped simply like the letter V with a small piece of hoop iron, the blade of a cutlass, or the leaf of a palm placed at the lower angle to form a spout to lead the milk into a receptacle below.

"A number of trees are treated in this manner and left to bleed for several hours. At the close of the day the rubber-gatherer collects all the milk, washes it by means of water, and leaves it standing till the next morning. He now procures a quantity of the stem of the moon-plant (Calonyction speciosum), pounds it into a mass, and throws it into a bucket of water. After this decoction has been strained it is added to the rubber milk, in the proportion of one pint to a gallon, or until after brisk stirring, the whole of the milk is coagulated. The masses of rubber floating on the surface are now strained from the liquid, kneaded into cakes and placed under heavy weights to get rid of all watery particles. When perfectly drained and dry, the rubber-cakes are fit for the market, and exported generally in casks. In Spainish Honduras, and other places in the Central America, instead of the juice of the moon plant, a solution of alum is used to coagulate the milk: but it is said that the injudicious use of alum tends to make the rubber hard and brittle, and to depreciate its value."

An indigenous plant, known as the "Green withe" of Jamaica yields excellent rubber, a specimen of which was sent to me by the Rev. Bassett Key.

This plant, probably a species of Echites, is found only in the interior woods of Manchester and St. Elizabeth, and, so far, I have been unable to obtain specimens in flower or fruit.

Dye Woods:—Of indigenous and natural dye woods the chief are Fustic and Logwood. The exports of these during the past year were:—Fustic 3,338 tons of the value of £10,014 and Logwood 29,770 tons of the value of £39,311. Logwood is not a native of Jamaica; it was introduced from Honduras by Dr. Barham, the author of Hortus Americanus in 1715. Since that, however, it has so established itself in the lowlands, especially on the lands in the neighbourhood of abandoned sugar estates, that it affords the basis of a not inconsiderable industry.

Of other dye-woods the East Indian Sappan is fairly common and might be propagated largely by seeds produced in the country. The Cam dye-wood from the West coast of Africa is rather scarce.

Pimento acris:—This is the Bay-Rum tree of the West Indies, the leaves of which are so largely used for the distillation of bay-oil—an ingredient of the favourite hair wash (Bay-Rum) of America. It is also used as a refreshing perfume in faintness or to sprinkle about sick rooms. These trees are very abundant in the Turks and Caicos Islands and a few plants have been raised at the Hope from seed obtained from thence.

Bitter-wood:—The demand for this wood (Picræna excelsa) has greatly increased lately, owing, it is said, to its utilization as a substitute for hops. The exports for last year were 1,815 tons of the value of £2,631.

The chips of this wood, known in England as Jamaica Quassia (to be distinguished, however, from Quassia amara, a native of Surinam, cultivated in Jamaica) is much used in cases of weak digestion where a simple bitter is required. Bitter cups, in which water allowed to remain for a short time acquire tonic properties, are also made from Picræna excelsa.

Bitter Bush:—This plant (Eupatorium villosum) common in many waste places in the islsnd has also come into prominence as a substitute for hops. It has an agreeable aroma and possesses a bitter principle which has long been recognized by the negroes. A very neat and compact preparation of this plant, made by an enterprizing planter into compressed cakes has been exported for experimental purposes, samples of which may be seen at the Museums of the Royal Garden, Kew, and of the Pharmaceutical Society of Great Britain.

Sago Palm:—This is the name under which several species of Cycads are known in the West Indies, one of which (Zamia pumila) is said to be indigenous to Jamaica. So far, however, I have been unable to find plants truly wild. One correspondent states that "Sago palms" are found growing wild on the beach at Ward's Bay to the east of Alligator Pond; whilst another gives Port Negril as a probable locality. Possibly some of my correspondents in the districts mentioned will be good enough to send me a specimen frond or a description of the plant so as to determine the question at issue.

Yellow Water-Lily:—This rare and interesting water plant (Nelumbium luteum) is said to have been found in lagoons in the parish of St. Catherine, but diligent search during the last three years has failed to discover it. Plants of the same species found in the district of Vere were said to produce rosy flowers.

I may mention that this water lily when in fruit possesses a long stalked torus or receptacle about three feet high, in which the black seeds are immersed. Plants with rosy flowers are established in the tank at the Parade Garden, Kingston.

The yellow-flowered form, which is much desired, was last gathered by the late Dr. Macfadyen in St. Catherine about 40 years ago.

Monstera deliciosa:—This plant fruited at Castleton during the past year.

Tree Tomato:—This is the popular name of a fruit naturalized in Jamaica and found in many old gardens in the

coffee districts of St. Andrew's and Manchester. By the kindness of Sir Joseph Hooker it has been determined as Cyphomandra betacea, a native of South America, including Peru and Chili, where also it is under cultivation. The plant (belonging to the natural order Solanaceæ) is of shrubby habit about 5 or 6 feet high. It is not generally known and seldom used in Jamaica, but it is without doubt a fruit that should be more largely cultivated as it answers in every respect the purposes for which the ordinary tomato is esteemed.

Plants are easily raised from seed which come into bearing in about two years. They are very prolific bearers and the fruit is available during the winter months, November to March when ordinary tomatoes are not so easily obtained.

Arracacha :—This umbelliferous food-plant (Arracacha esculenta) closely resembling the common parsnip was introduced to Jamaica in 1882 by Dr. Bancroft who obtained it from the neighbourhood of Bogota, United States of Colombia.

It is evidently indigenous to the high table lands of the Andean chain ; and thus it flourishes best in Jamaica in the Blue Mountain districts at elevations between 2,500 and 3,000 feet. Such situations would have mean annual temperature of 72° and 65° Fah. respectively with a mean annuals rainfall of about 100 inches.

The plant belongs, as mentioned, to the natural order Umbelliferæ and in appearance and habit of growth resembles the parsnip or celery. It is propagated either from seed or by "sets," the latter being off-shoots from the main stem, which are freely produced, and and grown with great facility. The valuable part of the plant is the root. During growth this gives rise to a number of small tubers or "fingers" eight or ten in number. The largest are from 8 to 9 inches in length and about 2 inches in diameter. They are yellow or white in colour, with a smooth surface, and marked, like the carrot, with transverse scars. At Bogota the main root is styled the madre, while the young edible tubercles or "fingers" are called hijos (or sons).

The youngest fingers are considered the best ; the older ones being fibrous and strongly flavoured

The plant is evidently very hardy and grows in almost any soil: it prefers, however, rich cool hollows, and in such situations is most prolific. I have seen it growing in stiff clay soils, as well as in those of a light sandy character, but under such circumstances the yield is not so great.

Tubers of this plant have been supplied to the Royal Gardens, Kew, for transmission to India and to British Colonies where no doubt this hardy and nutritious food plant might afford with little labour the means of sustaining life under very adverse circumstances.

In a trial experiment made my Mr. Hart the crop was reaped in seven months after planting ; the small plot (one perch in extent) yielded one hundred pounds weight of edible "fingers" which is at the rate of 7.14 tons per acre. A starch of fine quality is yielded by the tubers at the rate of 12 per cent. approaching the finest arrowroot.

Loquat :—This fruit tree known also as the Japanese Medlar (Eriobotrya japonica) is somewhat uncommon in the island and is found in fruit only, as far as I am aware, in the parish of Manchester. A young tree is doing well at King's House: and I have also seen one at Dr. Major's garden at Bath.

A short time ago I received a quantity of seed from Bermuda from which about 400 plants were raised. These are now established in pots and ready for distribution.

Oil of Ben :—Great interest is still being taken in the extraction of this oil from the seed of the common horse-radish tree (Moringa pterygosperma). Last year I took with me to England a fine sample of oil prepared by pressure by Mr. Kennedy. The report which I received from Messrs. Silver & Co. was as follows :—"It is an oil altogether unknown in this market, the sample is far from being bright and in its present state would be useless for either of the trades named in your memorandum.

"Whatever the oil may be in the West Indies, it appears to be very tender here, and although only about three parts congealed now would in the winter months be entirely so."

If Moringa pterygosperma yields the true Oil of Ben the preparation evidently must be different to that hitherto pursued ; and it is possible that the tender condition of the sample submitted to Messrs. S. W. Silver & Co. was owing to the presence in it of a large proportion of stearine which should be removed. At the Museum of Kew I saw a fine sample of "Oil of Ben" from Madras, made from the ordinary Moringa pterygosperma which was perfectly bright and clear even at the lowest temperature.

Dr. Schweinfurth, the eminent African traveller, at the request of Sir Joseph Hooker is in search of Moringa aptera in the Nile valley and if he is successful in finding it the question will then be soon solved whether the true Oil of Ben is the produce of this or the more common species.

In India a reddish gum exudes from Moringa pterygosperma which is used as a native medicine. No such gum has been noticed, as far as I am aware, in the West Indies.

Abyssinian Banana :—This giant member of the Banana family (Musa Ensete) is completely naturalized at the Government Cinchona Plantation at an elevation of 5,000 feet which has a mean annual temperature of 63° Fah. Some specimens are about 15 to 20 feet high, the central stem (with its investing sheaths of leaf petioles) often measures 2 feet 9 inches to 3 feet in diameter. The whole plant weighs more than a quarter of a ton without the roots and the fruit (a compacted mass about 2 ft. long and 1½ ft. in diameter) weighs about 60 or 70 pounds. The single carpels are about 4 ins. long of a pulpy but not edible nature, and contain 4 to 6 black seeds about half-an-inch in diameter.

This plant yields excellent fibre, and I have suggested elsewhere that it might be largely utilized for this purpose.

Tropical Pines :—Of Conifers Jamaica possesses only the Juniper Cedar (Juniperus Burmudiana) and the two Podocarps locally known as Yacca (Podocarpus coriaceus and P. Purdieanus).

At the Turks and Caicos Islands, Dependencies of Jamaica to the east of Cuba, there are one, if not two, species of Pinus which grow in gregarious masses almost at sea level. I have lately received some seed from these localities and raised plants which are doing well. Whether the pines at Turks Island is Pinus cubensis found in Cuba and supposed also to form the "pine ridges" of British Honduras remains to be seen. There are also P. occidentalis, said to be found in Cuba and San Domingo, and P. bahamensis described by Griesbach from the Bahamas.

Pecan Nut :—Through the kindness of Dr. Richardson I obtained, when in the Southern States of America, a large quantity of fresh seed of this handsome tree (Carya oliveæformis) which is nearly allied to the English Walnut. Plants are doing well at the Cinchona Plantation.

Common Cypress :—A fine tree of Cupressus sempervirens flourishes at the Cinchona Plantation, which has yielded a good crop of seed during the year.

Wild Tamarind :—This is the common name of a low plant (Leucæna glauca) from the small flat brown seeds of which breaches and bracelets are commonly made. The seeds are coloured black by means of copperas. Mr. Robert Russel of St. Ann's in reply to an enquiry informs me that horses feeding on the leaves of this plant completely lose the hair from their manes and tails ; and he adds, "horses from Llandovery, Richmond, and that side of the parish (of St. Ann) where the wild tamarind abounds are frequently to be seen tailless and maneless."

Sabadilla :—Seeds of this medicinal plant (Schœnocaulon officinale) have been received but as yet none have germinated. The Sabadilla is found in grassy places or open hills in Mexico, Guatemala and Venezuela, and I have long desired to naturalize it in similar situations in Jamaica. As the source of veratrum, which is a specific for external application in the form of ointment for rheumatism, neuralgia, and other painful affections, the sabadilla plant is worthy of attention.

Gynocardia odorata :—This tree yields the chaulmugri oil of Indian bazaars which is also a specific for rheumatism as well as in skin diseases and leprosy. The tree is not yet introduced to Jamaica, but seeds have been promised by Dr. King, of the Royal Botanic Gardens, Calcutta.

Negro or Maroon Coffee :—In the reports of the Royal Gardens, Kew, mention is made of the use of the seed of Cassia occidentalis as a substitute for coffee in tropical Africa as also at the island of Dominica in the West Indies.

From a letter received from the Rev. E. Bassett Key, I gather that the roots of this plant, which is very common in Jamaica, is being exported from Montego Bay as "dandelion."

Cow Tree:—Inquiry has been made for this tree (Brosimum Galactrodendron), which is a native of Venezuela. It is closely allied to the Bread-nut tree of Jamaica (Brosimum alicastrum) which also possesses a milky innocuous juice of an agreeable taste. The milk of the cow-tree, which, according to the report of the Royal Gardens, Kew, is obtained "by making incisions in the trunk, is said to have an agreeable taste like that of sweet steam with a slightly balsamic odour; it is somewhat glutinous, but said to be nourishing and perfectly wholesome. According to Boussingault the constitution of the "milk" of the Cow-tree approaches very closely that of the genuine milk of the cow."

A plant or two of this has been promised from Kew, which will be tried at the Castleton Gardens.

Australian Daisy:—This small but interesting composite of twining habit (Erigeron mucronatum) is really a native of Mexico, but it is known in hill gardens under the above name. It is the nearest in size and colour of all our composite plants to the European Daisy, which latter, however, is not naturalized in Jamaica.

Native Bread:—Under this name a curious tuberous body has been found at Cinchona by Mr. Hart, mostly in clayey soils, which has been identified as Myiitta lapidescens. This is a fungoid growth nearly similar to the "native bread" of Australia. Specimens of a similar body found at Travancore are used as medicine by the Chinese, but, like many other of their remedies, are of very doubtful utility. The largest specimens as yet found in Jamaica are about two inches in diameter. They are no doubt perfectly wholesome and when cut the fresh surfaces have much the appearance of compact boiled sago.

Baobab (Adansonia digitata):—A few specimens of this tree (somewhat resembling the cotton tree) are found in the island; where, as near Constant Spring (St. Andrew), they attain a large size and well deserve the name of "gouty stem" trees. The gourd-like fruit contains an eatble acid pulp. The wood is light, soft and of little use.

John Crow Beans:—This is the common Jamaica name for Crab's eyes or seeds of Abrus precatorius. "Under the name of Jequerity they have recently been used in the treatment of ophthalmia. They are very poisonous."

Horse Cassia:—This fine tree (Cassia grandis) a native of Brazil is rare in Jamaica. Specimens of fruit were lately received from Mr. Deans, Priestman's River, Portland; and seeds have been distributed to home and foreign correspondents.

Liquid storax:—A few plants of Liquidambar styraciflua, have been raised from seed received from the Department of Agriculture, Washington, which are doing well at the Cinchona Plantations. In the United States it is called sweet gum and the resin exudes from natural fissures or from incisions.

Strainer Vine:—This is a very common Cucurbitaceous plant in waste places in Jamaica; the fruit of which, under the name of Towel gourds has been exported of late. The close vascular network of the inside of this gourd (Luffa ægyptiaca) serves as a scrubbing brush and as an useful adjunct to the bath instead of a sponge. It is also worked up into light ornamental articles, baskets, &c., &c.

Mimusops Elengi:—A plant of this bears fruit freely at the Castleton Gardens. The fruit is said to be largely eaten in Guiana and elsewhere. The fragrant flowers are used for making garlands and the bark yields a tonic and febrifuge.

English Oak:—In the Blue Mountains the English oak is growing well. At Whitfield Hall two fine oak trees grow at the back of the house, one of which has a fine umbrageous head about 30 feet high and fully 40 feet in diameter: it has a clean stem about 6 feet in circumference at the base; other, but smaller, trees are found at the Cinchona Plantation and at Wallen's above Cold Spring coffee estate. This latter place had about a hundred years ago, a fine collection of temperate plants, whence, no doubt, they were gradually distributed over the neighbouring Blue Mountain districts. D. MORRIS.

31

OYSTER PRODUCTION AT ARCACHON.

[We have lately read so much of the non-success of attempts to breed oysters artificially, that it is refreshing to see what follows. Why should not the box method be adopted in the case of our pearl-yielding shells?—ED.]

The production of oysters in the Bay of Arcachon near Bordeaux, has, according to Consul Ward, become of late years a very important and lucrative branch of industry for the inhabitants, as well as the originators of the new method of breeding, which latter has had the result that the number of oysters now annually produced at Aracachon is greater than at any other place in Europe. During the year 1883, the number of oysters measuring at least five centimetres, or 1·95 inches in length and breadth, which were exported, is estimated to have reached about 173,000,000. The greater proportion of these were two or three years old, and were sold as "table" oysters, the remainder, though not inferior in size, were only one year and a-half old, and were forced by a peculiar process. This consists in placing the young oysters into so-called ambulances, that is, boxes with wooden sides and tops and bottoms, covered with galvanized wire, the boxes being fixed about a quarter of a yard above the ground. The oysters placed in these boxes grow about twice as rapidly as others which are merely placed in the beds. The chief reasons of the success of the Arcachon oyster beds are, on the one hand, the favourable condition of the water, which does not leave the beds dry for more than three hours at each tide, and thus causes the oysters to grow rapidly; and, on the other hand, the composition of the soil, a sort of blue clay, which is sufficiently hard to prevent the oysters from sinking down too deeply. The prolific production is also considered to be owing to the arrangement of tiles in the water along the sides of the oyster beds, the tiles having been previously dipped in a solution of lime; about 10,000 tiles are sufficient for a bed three acres in size, and after a short time from 50 to 1,200 oysters will collect upon each of the tiles. In consequence of the great productiveness of the Arcachon oyster beds, the French Government has lately prohibited oysters measuring less than five centimetres in length to be taken out of the bay for sale. The present price of oysters at Arcachon is considerably lower than 15 years ago, when only a few hundred thousand were exported annually; at the present date, oysters measuring over seven centimetres fetch from 55 to 58 francs per 1,000, compared with 120 francs in 1870.—*Journal of the Society of Arts.*

ANALYSIS OF RAIN WATER.

Analytical Laboratory, 79 Mark Lane,
London, E. C., June 12th, 1884.

No. 1.—Rain water received in a stone jar cased with wicker collected on Meeriabedde, Koslanda, Ceylon, between November 10th, 1883; and March 6th, 1884, and supposed to represent the 20·81 inches of rain registered between the above dates.

An Imperial Gallon was found to yield on evaporation, solid residue dried at 110° c = 5·74 grains, consisting of:—

Organic and Volatile Matters	1·12
Mineral Matters	4·62
Total ...	5·74

Also by direct determination—

	Per gallon.		Per acre for every inch of rain.	
Free Ammonia ...	·291	grains.		
Albuminoid Ammonia	·008	„		
	·299	„	equal to ·966	lb.
Nitric Acid ...	·510	„	„ 1·648	„
Sulphuric Acid ...	2·307	„	„ 7·458	„
Chlorine	·397	„	„ 1·283	„
Equal to Chloride of Sodium	·654	„	„ 2·114	„
Lime	1·332	„	„ 4·306	„
Magnesia	·100	„	„ ·323	„

Assuming that the average annual rainfall on the estate to be 90 inches—the total quantity of Ammonia from the above results would amount to 87 lb. in round numbers, and the Nitric Acid to as much as 148 lb.

These figures are so very high, and so much above what was found in the rain water collected by Mr. Walker of Bogawantalawa and reported on last November, that it would be desirable to make enquiry respecting the manner in which this particular sample was collected and stored between the 16th November, 1883, and 6th March, 1884.

From the accompanying table of rainfall, it will be noticed that the total of 20·81 inches extends over 42 days and has been made up by numerous showers, most of which are less than ½-inch; in only six instances did the quantity exceed 1 inch per day, and in these it varied from 1·35 to 3·52 inches. Doubtless the rain yielded by these showers does contain a much larger proportion of Ammonia and Nitric Acid to that found in water representing a heavy storm of from 3 to 6 or more inches of rain, but it would be desirable to make enquiries as suggested, especially as the relatively large quantity of mineral matters found on evaporation, leads me to conclude that some impurities had become accidently introduced.

For sending samples of water, clean white glass spirit bottles well corked are always to be preferred to stone jars.

(Signed) TOM GIBSON.

March 7th, 1884.

Analytical Laboratory, 79, Mark Lane, London, E. C. June 12th, 1884.

No. 2.—Rain Water received in a stone jar cased with wicker, collected on Walluha estate, in the district of Lindula, Ceylon, between August 1st and October 21st, 1883, and supposed to represent the 21·93 inches of rain registered between the above dates.

An Imperial gallon was found to yield on evaporation solid residue, dried at 212° F=67·20 grains, consisting of:

Fatty and Volatile Matters	..	55·44 grains.
Mineral Matters	.. ..	11·76
Total		67·20

The water had a strong acid reaction, with a very disagreeable rancid smell, and a decided yellow appearance. It was evidently not pure rain water, but was contaminated with fatty matters, while the mineral residue contained over 4 grains of Lime, 2 grains of Oxide of Iron and Alumina, and nearly 5 grains of Sulphates. On breaking open the stone jar, the interior was found thickly coated with partially decomposed fatty matter.

Under these circumstances it was useless to proceed further with the analysis for Ammonia and Nitric Acid, as the results could not be of any practical value.

JOHN HUGHES, F. C. S.,
Fellow of the Institute of Chemistry.

GOSSIP ABOUT SULU.

White coral and lava lie about the town a good deal, but it cannot be considered good paving material. The freshest and coolest streams of fresh water are plentiful, and there is an abundance of fruit, of which a large quantity is exported to Singapore but by far a larger quantity rots on the ground. Cockatoos, and green parrots are flitting about everywhere. There is no jungle,—only here and there a line clump of trees, the remainder of the soil being uncovered except by grass. Nothing could be more like a fine English park from the appearance of the land, and the chances are that whilst you are looking at it a deer or two will bound across the view. A bastard teak grows on the hill sides, palms are plentiful, copra is largely exported to Singapore and a soap tree grows largely. What a treat the exploration of the whole place would give a botanist. Flowers grow everywhere; recently some orchids were sent from here to H. R. H. the Prince of Wales by special command. There is only one plantation worth noticing, and that is a very fine one, on which grows hemp, coffee, cacao and sugar, to perfection.

The most important product has yet to be mentioned, and that is pearls, mother of pearl and other valuable shells. Mr. Streeter has an agent here, and through his courtesy I witnessed some important transactions. The rule regarding pearls is said to be that all pearls are to be first submitted to the Sultan; if he wishes to buy his offer in not disputed, or the pearl finder would be punished and the gem confiscated. So all trade in this article is done *sub rosâ* but notwithstanding the great cunning of some Chinese buyers they get caught sometimes and then!—The pearl shells in the rough and unsorted are worth from $30 to $45 per picul. They make very attractive wall decorations when treated as I saw some; they were about 10 in. in diameter and were spotless. Several were painted very fairly by the amateurs of the island. Some of the shells had also bright little water color figures cut out and stuck on them. The Sulu diver is said to be the best in the world; he can dive in 18 fathoms. I timed one man under water 4 4-5th minutes.—*China Mail.*

CINCHONA OFFICINALIS has flowered well in the Brisbane Botanic Gardens. As this is the first instance of the cinchona flowering in Queensland, it is particularly worthy of note, indicating as it does the suitability of the climate for its growth, and the prospect of Queensland in the not very distant future contributing towards the supply of cinchona bark for the markets of the world. The tree in question, about five feet in height, is quite hardy with ordinary cultivation in the open ground, and may be considered a fair success.—*Madras Mail.* [As we know to our cost in Ceylon, the early flowering of the cinchona tree is an adverse rather than a favourable sign.—ED.]

Correspondence.

To the Editor of the Ceylon Observer.

CINCHONA CULTIVATION: LEDGERS.

Western Ghats, 4th July 1884.

DEAR SIR,—I am sorry to see that the subject of cinchona is gradually dropping out of discussion in your columns, because, I fear it, argues that its cultivation must be becoming looked upon as a non-paying concern. I have been very anxious to hear the opinions of those of your subscribers who had tried the "Java Ledger" seed, sold by auction in Colombo during the earlier half of 1882, having heard opinions expressed that have made me doubtful whether the resulting plants are Ledgers at all, or "Micranthas" or some other comparatively worthless variety. Some of the plants grown from that same seed, and put out in estate a year or less since, are commencing to flower, and, when they do, I dare say I may be able to identify them, at all events determine if "Ledgers" or not. I should be very much obliged if any of your readers would inform me whether the fact of their blossoming at so early an age *necessarily* condemns their claim to being so as unfounded? I have the most undoubted 'Ledgers" (from "Yarrow" seed) of a similar age and size without a sign of flowering in any one of them. I have also "Verdes" with same result, no buds. Cinchona cultivation is one of great interest to many in Mysore, who, I am sure, regret that recently the *T. A.* has afforded them so little information to lead them to decide what its prospects are. I am lamenting the non-arrival of your June issue.—I am, dear sir, yours faithfully. MAHSEER.

TRADE ALLOWANCES ON TEA.

Ambagamuwa, July 20th, 1884.

DEAR SIR,—Information on the following subject would be of interest to all concerned in tea, viz, the "trade allowances." I believe 2½ per cent is the utmost supposed to be demanded. But when it amounts to 5 per cent and 8 per cent, as it has done of late, I think there is just cause for complaint. What is your own experience, Mr. Editor? Are you mulcted to the same extent? 5 per cent on the last year's crop from Ceylon would be 75,000 lb., a nice perquisite for the trade!—Yours faithfully, A VICTIM.

[Since we drew attention to the shamefully exorbitant charges that were being made upon our tea, we have personally nothing to complain of. The local agency commission is only 1 cent per lb., and the deductions from the quantity of tea made by the brokers in the London market, which is what our correspondent evidently refers to, are about 1 lb. in every 177, or say half-a-pound per chest. We do not think anyone can grumble at that.—ED.]

THE PAPPAYE OR PAPPAWE.

DEAR SIR,—Can any of your readers give me any information as to how the juice or milk of this fruit is expressed, and what the value of the same would be at home? If the tree is of any value, something might be made out of it, as it grows readily in almost any soil, and, when once planted amongst the coffee, becomes a regular weed in time. The fruits, both ripe and green, are used by the coolies as food. I have a great number of these trees growing through my coffee, and I knew that coolies are attracted to the estate by these and jak fruit. If it is possible to get any sale for the expressed milk, I could in a very short time extend the cultivation of this product.—Yours truly, B. G.

[Some correspondent will probably be good enough to give the desired information.—ED.]

HAPUTALE PLANTING REPORT.

Haputale, 21st July 1884.

DEAR SIR,—By today's tappal you will receive a small tin box containing a few insects, two species, their *names and origin may be of interest to your readers.*

Coffee in lower Haputale has lately been the subject of a smart attack of leaf-disease, but is now showing signs of recovery. Several fields of young coffee which suffered last year have been singularly free from any attack this year: the upper fields have as yet suffered but little, and wood is getting into prime order, and on both upper and lower fields a healthy looking spike is pretty general. The leaves of the young coffee bearing heavily have a flabby appearance, and of the branches a large proportion have black points, the result of the long spell of dry weather. It is comforting to know that old residents seem to agree that this is the kind of weather which in days gone-by used to give the bumper crops with a large percentage of light coffee in autumn, but the spring crops were so large and of first quality that the loss from the lights in autumn was never felt.

Crop from the early blossom is now of a straw color, and, with a few heavy showers, picking will likely be commenced in earnest on the lower estates about the middle of August. About the same time, the first good blossom for spring crop may be expected.

Cattle sent to graze must have a hard time of it, grass is looking very parched, and even those which are stall-fed must find their supply reduced and inferior.

Roads.—The Lemas road is now in very good order and the contractor deserves credit for the energy recently displayed. Estate roads generally are also being repaired, and one can get about without the risk of coming to grief.

Weeding.—Have never seen Haputale estates in better order. Contractors must be making money, if the average cost of weeding is over the rupee per acre per mensem.

New Products.—Seeing that in this important district there is so much fine coffee, new products are having a fair share of attention given them, and shows there are proprietors determined to make the most of their estates with the material at hand, since Government have been so lax in providing railway-carriage for manure up to maintain these fine properties.

Cacao in the Kandapola section appears to be doing well. Where planted in a sheltered situation, there are trees fully seven feet in height and about twenty months old, while the average is about five feet. Having an opportunity of carefully inspecting a field of about ten acres of young cacao, with a view to learn whether any of the pests had visited it, two plants only, of about 18 inches in height, showed signs of weakness, the leaves of one of them were mere skeletons; and the peculiar-looking insects sent in tin box were picked off them; the other plant had a brownish-looking leaf-bud, and under it was found the dark-red insect with the two short feelers and four lines of light spots across the back. The former wretches appear to be beetles with a sort of shield or covering all round, from which they pull themselves half out before they creep along. Are these the Helopeltis? If so, the damage they do is totally different in appearance from that done by wind. As these were all collected from one plant and no more could be found in the clearing, it should not be a difficult task to keep them in check. Those who have land in Haputale suitable for cacao cultivation have no cause to be alarmed, but, from the rapid growth of the plant and the bearing properties of the older trees, they have every encouragement to carry on the cultivation, the mistake some have made is in planting cacao where the wind tears off

not only the leaves but the points of the branches. Cacao evidently grows well in Haputale without shade, but not without shelter from wind.

Cardamoms appear to be one of the favourite new products. Although they grow fairly well in good soil in the open, it is advisable to plant some quick-growing shade-trees, and perhaps the cotton tree will be found as suitable as any. Crop is now being gathered off a clearing not two years planted.

Ceará rubbers continue to grow apace, but those who claim to have experience of tapping say there are no trees old enough for operating upon.

Cinchonas.—Harvesting on an extensive scale has been carried on lately : 50,000 lb. of dry bark is now being dispatched from one of the Company's estates. Some estates are coppicing their trees to make way for tea, and others are shaving younger trees to keep the kettle boiling.

Tea.—As it has been satisfactorily proved to some minds that this product will grow and flush well on the higher estates, many have now large tea nurseries, and a considerable addition to the tea acreage will be made during October and November. One of the largest proprietors of coffee in Haputale, and who knows well what he is about, is now felling 50 acres of forest, the lower portion of which, it is said, he intends planting with coffee and the upper with tea. The general opinion here is that all the higher forest-lands in Haputale are thoroughly suitable for tea-cultivation. Even on a poor piece of patana soil under the Pass, can be seen some very healthy tea bushes, and until lately loaded with crop ; these bushes appear to have been kept for seed, and no information could be obtained as to whether on such soil in Haputale there would be a sufficient number of flushes to make tea pay ; but there can be no doubt as to the fact that on patana soil too poor to grow coffee, there the tea now flourishes.—Yours truly,

PLANTER.

THE PAPPAYA OR PAPPAWE.

DEAR SIR,—In reply to "B. G." there is no difficulty in collecting the milk of the above-named fruit as it exudes from the green fruit freely on incision, but I do not know how it is preserved or what it may be worth.

It is well-known that this milk has all the principles of *pepsine*, and I have heard that it enters largely into the manufacture of that medicine.—Yours truly,

ALPHA.

COFFEE AND TEA IN SOUTH INDIA.

Kotagherry, Nilgiris, 28th July 1884.

DEAR SIR,—Coffee prospects this season in Ceylon, though bad enough in parts, yet seem better than ours. Many estates here, from the appearance of the blossom, late though it was, expected bumper crops, but the failure of the rain has now quite settled anything of that sort, and certainly the majority of estates will not pay expenses. Tea is not quite so badly off, but the outturn is unusually short on most places. The same cry comes from Coonoor, Ouchterlony Valley and Wynaad, though I did hear of a group of favoured estates in the latter district which had rain at the right time and would do well. Having no S. W. monsoon we have naturally done no planting, and the long drought has brought out bug on many coffee estates. Cinchona is doing pretty well. It seems to be a general opinion that your large average yields of tea in Ceylon will not continue. I should say that it depends entirely on yourselves, whether you manure properly or not.

One thing that strikes any one reading the *Observer* is the large amount of crime and lawlessness in Ceylon. Planters in Southern India would most certainly go in for a little (or a good deal) of lynch law *on the quiet*.

I have tried both Jackson's and Kinmond's rolling machines, improved forms, and prefer the latter. It does not express the juice, and I think rolls better all round.—Yours faithfully,

PLANTER.

DIRECTIONS FOR MAKING TEA PROPERLY.

DEAR SIR,—Why do not superintendents of estates and vendors of tea generally affix "directions for use" on their packets of tea, just in the same way as is done in the case of Brown & Polson's corn flour, Crosse & Blackwell's goods, tinned meats and the thousand and one such like articles. It is well-known that but very few people know how to "make tea" properly, and frequently good tea is spoiled by being badly infused. Especially is this so with Ceylon tea, which requires much less of it than China and which is completely spoiled by being made "strong."

Y.

THE CULTURE OF ARROWROOT.

Arslena, Nawalapitiya.

DEAR SIR,—A friend of mine down in the Straits Settlements has sent me the following estimate for opening one acre of an arrowroot garden, and wishes to know why the European does not cultivate the root as it is a thing that always sells well. His estimate is in $ and cts., but I have put it into rupees and cents :—

Price of land	...	R 20·00	
Felling, clearing	...	20·00	
Pegging	...	5·00	
Holing 5,000 holes 3 x 3	...	41·50	
Filling in	...	5·00	
Planting	...	5·00	
Value of plants	...	25·00	
Weeding 12 months	...	12·00	
Buildings	...	50·00	
Machine	...	50·00	
Sundries	...	20·00	
1st year's expenditure	...	...	R253·50
2nd year : Weeding	...	R 12·00	
Planting	...	5·00	
Manure	...	30·00	
Sundries	...	100·00	
2nd years' expenditure	...		R147·00
			R400·50

1st year 5,000 plants give say 3,000 lb.
2nd year do de do 3,000 lb.

6,000 lb.

At 35 cents per lb.	...	...	R2,100
2nd year's expenditure	...	...	400
			R1,700

This is my friend's estimate, £170 per acre clear profit. His advice is to have a flat lay of land near a stream and by no account to open more than 10 acres at a time, unless you have a very powerful set of machinery You can root out the arrowroot twice a year. He has had five crops in two years. For drying the flour his advice is to put up a small kiln to dry it, as it has to be done at once or it will spoil.

Should any person feel inclined to open a small place, I can give him further information, or he could give it to me to open for him.

I expect another letter from him about the cultivation of ginger, and when it arrives I will let you know what he says.—Yours faithfully.

W. M. P.

P. S.—Arrowroot plants are to be had very cheap

in the villages for about 50 cents per hundred. The reason he estimates the value of the flour for (35cts.) is that there will be a great demand at such a low price, but he has sold a great deal to the medical department at $\frac{1}{2}$ per lb.

[In Ceylon, arrowroot is liable to the attacks of rats, and we doubt if the quality of the starch could compete with that of West Indian. We suspect that but little profit is made by cultivators of arrowroot or tapioca on a large scale. Sago culture is not so costly and the flour is used in England as food for calves.—ED]

REVENUE FROM THE SEA.

DEAR SIR,—Trepang or *bêche-de-mer* as a source of revenue may be defended from circumstances other than its being an article only of luxury. Apart from its being an object of industry to a few indigent people, it may be argued that it is obtained by only one set of people who employ the poor people to pick them up. The process can scarcely be said to be fishing: no effort is required, as in shallow water they have only to put down their hands and pick them up, or in deep water they are harpooned or dived for. The slugs lying in a dormant state offer no resistance, and the facility for taking them up is consequently very great. Being so easily taken up, a few of the Moors cure and export them to China, where it is said that only the wealthy people can afford to purchase and enjoy them; the article must therefore be sold at a very high price there. Reckoning the estimated value set here as R10 a cwt. it is a great question at how many hundred per cent a cwt. they are sold in China as when arrived there the Chinese merchants buy them wholesale, assort and clean them, then they are rolled up in paper one by one and exhibited in their shops for sale at a very high price; hence it is that only the rich people can enjoy it. The estimated, or rather the nominal value of *bêche-de-mer* is said to be R10 and is exported free of duty (although it appears that only a few cwts. are fished and exported, yet careful enquiry will, no doubt, elicit the fact that it is some tons and not cwts.) The proceeds of these sales are secured by a few Moormen which are all converted into silver, and it is a known fact that by far the largest amount of silver they recover in the island is carried away to India, whereby much of the silver coinage instead of being circulated in the colony is removed.

Were the right for fishing the slug sold, or a share at least of the local value secured, Government will secure a part of the money which is otherwise taken away. Without a trial, it is impossible to know what is the actual value of the slug, the quantity fished, or what enormous profit the shippers to China realize.

The pearl-fishery in some places yields a large and in other places a small revenue, but this is a more precarious speculation, seeing that there is more danger and trouble in fishing and the uncertain quantity and value of the pearl that may be procured, which cannot be said of *bêche-de-mer*.

As an industry at present the coolies earn but a precarious pittance as the fishery is not regular and it is a question whether the coolies themselves are reasonably and regularly paid; whereas, if the rent is sold, it will be for the interest of the renter to employ people regularly during the season (that is, before the setting-in of the south-west monsoon) when the slugs are more easily fished.

Hitherto the only marine productions which yield a revenue have been salt and pearls; it need not be considered difficult or mean to add the other resources of the sea to the revenue of the colony (fish being an article of necessity for food should always be exempted). It is well-known that chanks and shells afford a lucrative trade; then there is sponge which when recovered and properly prepared will also form an article of trade.

Some time ago there was a great demand for Rocella (*Rocella tinctoria*) which yields a beautiful purple dye; a sea weed* which is constantly procurable on the rocks and sea-beach in the Southern Province. Then there is the Jaffna moss so useful for invalids.—Yours truly TREPANG

[We take it for granted that the Customs officer in fixing R10 per cwt. as the local value of the sea-slug have taken note of the actual selling value in China, and therefore even R1 per cwt. on 450 cwt. would not be worth the trouble of collecting. The idea that any quantity is smuggled away is absurd. —ED.

PAPAW JUICE.

DEAR SIR,—If your correspondent will refer to Mr. Thos. Christy, No. 119, Fenchurch Steet, London, he will obtain reliable information on the subject. I corresponded with Mr. Christy on this same subject about two or three years ago and his reply was discouraging at the time. There was no great demand then, although papaw juice was used for the manufacture of pepsine at the time. I believe it is imported largely from the West Indies, as is the case with pine apples.

The juice of the fruit alone should be collected and then dried between two strips of glass. At least, that is my present recollection of Mr. Christy's instructions. I cannot lay my hand on his letter readily, or I would send you copy of instructions for collecting the juice.—Yours faithfully,

JAS. H. BARBER.

PLANTING NOTES FROM MYSORE: THE CLIMATES OF CEYLON AND MYSORE COMPARED.

DEAR SIR,—I was much interested in the account of the discussion at the big Planters' Association meeting at Kandy on this new disease called "*fly*" that has attacked or is said to have attacked cacao. It bears on a point to which I had for a long time given my attention before I left Ceylon, and more earnestly since I came to Mysore and had an opportunity of seeing cultivation maintained on a different basis than in Ceylon.

As far as I can make out in India and Ceylon, but especially in the latter, wherever there is constantly a state of a moisture-laden atmosphere, there *shade* becomes an unimportant factor. But where this continuous moistness does not exist, notably on the plateau of Mysore, shade is the chief and most important means of preserving an estate from the wear and tear of climate. In short, in wet climates, one must not permit any light, air and sun or evaporations to be lost which would help to remove excessive wet, nor neglect a careful system of drainage. On the other hand, in a climate that has long periods of dry weather, one must not dare to risk the terrible ordeal of fiery cloudless heat that annually recurs without an umbrella of foliage.
